# NUTRITIONAL MANAGEMENT OF RENAL DISEASE

---

FOURTH EDITION

*Edited by*

JOEL D. KOPPLE

*The Lundquist Institute at Harbor-UCLA Medical Center, David Geffen School of Medicine at  
UCLA and UCLA Fielding School of Public Health, Torrance and Los Angeles, CA, United States*

SHAUL G. MASSRY

*Professor of Medicine, Physiology and Biophysics, University of Southern California, Los Angeles, CA, United States*

KAMYAR KALANTAR-ZADEH

*Harold Simmons Center for Kidney Disease Research and Epidemiology, Division of Nephrology, Hypertension and Kidney Transplantation,  
Department of Medicine, University of California Irvine School of Medicine, Orange, CA, United States;  
Nephrology Section, Department of Medicine, Tibor Rubin Veterans Affairs Medical Center, Veterans Affairs Long Beach Healthcare System,  
Long Beach, CA, United States;*

*The Lundquist Institute at Harbor-UCLA Medical Center, Torrance, CA, United States;  
Department of Epidemiology, UCLA Fielding School of Public Health, Los Angeles, CA, United States*

DENIS FOUQUE

*CarMeN Laboratory, INSA-Lyon, INSERM U1060, INRA, University Claude Bernard Lyon 1, Villeurbanne, France;  
Department of Nephrology, Nutrition and Dialysis, Hospital Lyon-Sud, Hospices Civils de Lyon and University Claude Bernard Lyon 1, Lyon, France*

List of contributors	xvii	Insulin secretion	31
About the editors	xxi	Insulin clearance	32
Preface	xxiii	Hypoglycemia	32
		Carbohydrate metabolism in patients with renal replacement therapy	33
		Treatment of diabetes mellitus in diabetics with chronic kidney disease	34
		Drug management in diabetics with chronic kidney disease	35
		References	37
 <b>I</b> <hr/>			
<b>Normal and altered metabolism of chronic kidney disease</b>			
 1. The KDOQI Clinical Practice Guidelines for Nutrition in CKD: 2020 update	 3	 4. Altered lipid metabolism and serum lipids in chronic kidney disease	 43
T. ALP IKIZLER AND LILIAN CUPPARI		NOSRATOLA D. VAZIRI, HAMID MORADI AND YING-YONG ZHAO	
Introduction	3	Introduction	43
The guideline development process	3	References	55
Key points addressed in the 2020 updated guideline	5		
Conclusion	7	5. Energy metabolism and requirements in chronic kidney disease	61
References	7	MACKENZIE K. CERVANTES AND RACHELLE BROSS	
 2. The influence of kidney disease on protein and amino acid metabolism	 9	Introduction	61
BIRUH T. WORKENEH AND WILLIAM E. MITCH		Energy balance	61
Introduction	9	Overview and recommended energy intake in chronic kidney disease patients	70
Influence of protein intake on CKD	10	Abbreviations	71
Dietary restriction of protein	10	References	71
Metabolic acidosis	11		
Role of protein metabolism in hypertension	14	6. Uremic toxins: an integrated overview of classification and pathobiology	77
Uremic toxins derived from protein metabolism	14	RICHARD J. GLASSOCK AND SHAUL G. MASSRY	
Dysregulation of proteolytic pathways in CKD	16	Introduction	77
Albumin and other markers of malnutrition	19	Definition of a uremic toxin	77
Protein supplementation in dialysis	21	Classification of uremic toxins by physicochemical characteristics	79
Protein metabolism post-kidney transplantation	22	The pathobiologic categorization of uremic toxins according to the processes underlying accumulation in body fluids	83
Conclusion	22	The linkage of uremic toxins to the pathobiology of uremia	83
References	23	Clinical manifestations of uremia and the role of tropisms	84
		The effects of diet and dialysis on uremic toxins	84
 3. Carbohydrate metabolism in chronic renal disease	 29	Summary and conclusion	85
MARCIN ADAMCZAK, EBERHARD RITZ AND ANDRZEJ WIECEK		References	86
Introduction	29		
Insulin resistance	29		

[illegible]

14. Prevention and management of cardiovascular disease in kidney disease and kidney failure	207	18. Therapeutic strategies to limit tryptophan metabolites toxicity during chronic kidney disease	281
PRANAV S. GARIMELLA, DANIEL E. WEINER AND MARK J. SARNAK		CHRISTOPHE BARBA, DENIS FOUQUE AND LAETITIA KOPPE	
Introduction	207	Introduction: Gut-derived uremic toxins	281
Cardiovascular risk factors	207	Metabolism of tryptophan and indole production	281
Management of CVD	214	Tryptophan metabolites as aryl hydrocarbon receptor ligands	282
Conclusion	217	Tryptophan metabolites promote CKD progression	283
References	218	Role of organic anion transporters in the nephrotoxicity of tryptophan metabolites	285
15. Effects of nutritional status and changes in nutrient intake on renal function	225	Tryptophan metabolites induce a vascular procoagulant phenotype and cardiovascular complications	285
YOKO NARASAKI AND CONNIE M. RHEE		Tryptophan metabolites and cardiovascular events in CKD patients	287
Introduction	225	Tryptophan metabolites involved in musculoskeletal disorders	287
Impact of nutritional status on kidney function	226	Therapeutic strategies to reduce tryptophan metabolites accumulation and production	288
Impact of protein-energy wasting on kidney function	234	Conclusion	291
Effects of maternal nutrition on renal development	239	References	291
Conclusion	239		
References	239		

### III

#### Nutrition and slowing of progressive chronic kidney disease

16. Dietary interventions to slow the progression of chronic kidney disease and improve metabolic control of uremia	249	19. Alkalization to retard progression of chronic kidney disease	297
DENIS FOUQUE		NIMRIT GORAYA, KALANI L. RAPHAEL AND DONALD E. WESSON	
Assessing the progression of chronic kidney disease	249	Introduction	297
Protein intake and chronic kidney disease:		The daily H <sup>+</sup> challenge	299
Experimental data	252	Maintenance of normal acid–base homeostasis	301
Dietary protein intake: Clinical studies	255	How might clinicians approach management of H <sup>+</sup> stress, as a kidney protective intervention, in individuals with CKD within the context of the three mechanistic strategies?	306
Clinical evidence of the effects of low-protein diets	262	Conclusion	306
Conclusion	267	Funding	306
References	267	References	306

### IV

#### Mineral and vitamin metabolism in kidney disease

17. Disorders of phosphorus homeostasis: emerging targets for slowing progression of chronic kidney disease	271	20. Nutritional management of sodium, chloride, and water in kidney disease and kidney failure	313
ORLANDO M. GUTIÉRREZ		MICHEL BURNIER SR.	
Introduction	271	Introduction	313
Role of dietary phosphorus intake in disturbances of mineral metabolism in CKD	271	Regulation of sodium, chloride, and water in healthy conditions	313
Disorders of phosphorus homeostasis and kidney disease progression	272	Regulation of sodium, chloride, and water in kidney diseases (stages 3–5)	316
Dietary phosphorus restriction in CKD: practical considerations moving forward	275	Regulation of sodium and water balance in kidney failure (CKD stage 5D)	317
Conclusion	276	Clinical implications of salt and water excesses in kidney diseases	318
References	276	Recommendations for the nutritional management of sodium, chloride, and water	321

X	Contents	
Conclusion	325	Interventions to target lowering of phosphate and FGF23 388
References	325	Summary 392
		References 393
21. Management of potassium in chronic kidney disease and acute kidney injury	329	25. Vitamin D in kidney disease 397
DAVID E. ST-JULES AND ANUJA SHAH (PRADIP)		JULIA SCIALLA
Potassium balance in health	329	Introduction 397
Potassium balance in kidney disease	331	Normal vitamin D metabolism and functions 397
Assessing potassium disorders	333	Vitamin D physiology in CKD 401
Managing hyperkalemia	334	Detailed sources of vitamin D and burden of vitamin D deficiency 401
Managing hypokalemia	339	Outcomes associated with vitamin D deficiency 402
Case study—hyperkalemia in chronic kidney disease	339	Supplementation of vitamin D 402
References	341	Vitamin D supplementation in special CKD populations 405
		Current controversies and summary recommendations 406
		References 406
22. Magnesium and kidney disease	345	26. Vitamin metabolism and requirements in chronic kidney disease and kidney failure 413
MUGUREL APETRII, ADRIAN COVIC AND ZIAD A. MASSY		CHARLES CHAZOT, ALISON L. STEIBER AND JOEL D. KOPPLE
Introduction	345	Vitamin A, physiology, biochemistry, and nutritional status in chronic kidney disease patients 413
Serum magnesium in chronic kidney disease	345	Vitamin E, physiology, biochemistry, and nutritional status in chronic kidney disease patients 419
Modulation of serum magnesium in chronic kidney disease patients	346	Vitamin K, physiology, biochemistry, and nutritional status in chronic kidney disease patients 423
Magnesium and outcomes	347	Vitamin B1 (thiamine), physiology, biochemistry, and nutritional status in chronic kidney disease patients 427
Nutritional aspects	348	Vitamin B2 (riboflavin), physiology, biochemistry, and nutritional status in chronic kidney disease patients 430
Conclusion	348	Vitamin B6 (pyridoxine) physiology, biochemistry, and nutritional status in chronic kidney disease patients 431
References	349	Vitamin C (ascorbic acid), physiology, biochemistry, and nutritional status in chronic kidney disease patients 436
		Folate (vitamin B9), physiology, biochemistry, and nutritional status in chronic kidney disease patients 441
23. Calcium, phosphate, PTH, vitamin D, and FGF-23 in CKD-mineral and bone disorder	353	Vitamin B12, physiology, biochemistry, and nutritional status in chronic kidney disease patients 447
EZEQUIEL BELLORIN-FONT, ALEXANDRA VOINESCU AND KEVIN J. MARTIN		Niacin (vitamin B3) physiology, biochemistry, and nutritional status in chronic kidney disease patients 448
Calcium metabolism	353	Biotin (vitamin B8) physiology, biochemistry, and nutritional status in chronic kidney disease patients 451
Vitamin D	354	Pantothenic acid (vitamin B5) physiology, biochemistry, and nutritional status in chronic kidney disease patients 452
Phosphate metabolism	355	General comments regarding vitamin supplements in kidney disease 453
Parathyroid hormone	357	Conclusion 455
Fibroblast growth factor-23 and Klotho	358	References 455
Alterations in mineral metabolism in CKD	359	
Control of serum phosphate in CKD	363	27. Trace elements, toxic metals, and metalloids in kidney disease 467
Therapy with vitamin D sterols	370	SUNDARARAMAN SWAMINATHAN AND MANISHA SINGH
Calcimimetics	371	
Parathyroidectomy	373	Introduction 467
Conclusion	373	
References	373	
24. Phosphorus metabolism and fibroblast growth factor 23 in chronic kidney disease	383	
ANIP BANSAL AND MICHEL CHONCHOL		
Phosphate metabolism in health	383	
Phosphate metabolism in chronic kidney disease	383	
FGF23's structure, synthesis, and function	384	
FGF23 in chronic kidney disease	385	
Role of phosphate and FGF23 excess	386	

Trace elements	467	Dietary phosphorus	529
Trace element functions	467	Dietary calcium and vitamin D	531
Overview of trace elements in kidney disease	468	Vegetarian diet, fibers, and the microbiome	532
Conclusion	481	Carbohydrates, fats, and dietary energy	532
References	481	Dietary management of acidosis in kidney disease	532

28. Nutritional and nonnutritional management of the nephrotic syndrome	491	30. Use of dietary therapy in far-advanced chronic kidney disease to delay renal replacement therapy or facilitate incremental dialysis transition	545
ALESSIO MOLFINO, MARIA IDA AMABILE AND GEORGE A. KAYSEN		NORIO HANAFUSA, KAMYAR KALANTAR-ZADEH AND JOEL D. KOPPLE	
Introduction	491	Introduction	545
Albumin homeostasis in the nephrotic syndrome	491	Protein intake	546
Dietary protein	492	Energy intake	546
Effects of the nephrotic syndrome on solid tissue proteins	496	Importance of monitoring the patient	548
Dietary proteins as potential allergens responsible for renal disease	497	Benefit beyond dialysis initiation	549
Effects of lipids on renal disease and nephrotic syndrome	497	Dietary therapy for incremental or infrequent dialysis	550
Derangements in divalent cation metabolism in the nephrotic syndrome	501	Future directions	553
Derangements in salt and water metabolism in the nephrotic syndrome (volume homeostasis)	501	References	554
Recommendations for nutritional and nonnutritional treatment of the nephrotic syndrome	504	31. Nutritional management of maintenance hemodialysis patients	557
Acknowledgments	506	RAMANATH DUKKIPATI, LEONARDO SPATOLA, KAMYAR KALANTAR-ZADEH, ANUJA SHAH (PRADIP) AND JOEL D. KOPPLE	
References	506	Introduction	557
29. Nutritional approaches and plant-dominant diets for conservative and preservative management of chronic kidney disease	515	Assessment of nutritional status in maintenance hemodialysis patients	559
SHIVAM JOSHI, AMANDA BROWN-TORTORICI, ELIZABETH J. SUSSMAN-DABACH AND KAMYAR KALANTAR-ZADEH		Acidemia and protein wasting	565
Introduction	515	Goals of nutritional management in maintenance hemodialysis patients	565
Dietary protein in kidney disease	515	Dietary nutrient requirements	565
High-protein diets may be harmful to kidney health	517	References	582
An LPD preserves kidney function	517	32. Nutritional management of chronic peritoneal dialysis patients	593
Plant-based foods have a favorable impact on kidney health	519	CARLA MARIA AVESANI, OLOF HEIMBÜRGER, PETER STENVINKEL AND BENGT LINDHOLM	
Benefits of a plant-dominant LPD	519	Introduction	593
Features of PLADO regimens	521	Main nutritional disturbances in patients undergoing peritoneal dialysis	593
Safety and adequacy of a PLADO	522	Assessment of nutritional status in peritoneal dialysis patients	597
Impact of PLADO on microbiome in CKD	523	Nutritional counseling and recommendations for peritoneal dialysis patients	598
Similarities and distinctions between PLADO and other CKD diets	523	Healthy diet for peritoneal dialysis patients: an important concept that has been neglected in the renal diet	603
Role of dietitians in PLADO	523	Conclusion	604
Recommendations for practical implementation of PLADO	524	References	604
Concurrent pharmacotherapy and other interventions	524	Further readings	606
Laboratory tests for nutritional management of CKD	525		
Suggested self-administered questionnaires	526		
Diet safety and transient dietary regimen suspension	527		
Challenges and pitfalls of the dietary management of CKD	527		
Dietary sodium and fluid intake	528		
Dietary potassium	529		

<b>33. Nutritional management of kidney transplantation</b>	<b>607</b>	Parenteral nutrition in acute kidney injury	675
MARIA CHAN AND STEVEN CHADBAN		Complications of nutritional support in patients with acute kidney injury	678
Introduction	607	Monitoring nutritional support in patients with acute kidney injury	678
Pretransplant factors affecting posttransplant outcomes	607	References	679
Nutritional considerations for kidney transplant recipients	611		
Other nutritional issues	619	<b>36. Nutritional prevention and treatment of urinary tract stones</b>	<b>685</b>
Current trends and latest topics of interest	619	NEERA K. DAHL AND DAVID S. GOLDFARB	
Conclusion	622	Epidemiology of stones	685
References	623	Risk factors	685
		The gut microbiome	686
<b>34. Nutritional management of the child with kidney disease</b>	<b>629</b>	Stone formation	686
VIMAL CHADHA AND BRADLEY A. WARADY		Goals for the treatment of recurrent stone formers	686
Etiology of malnutrition	630	Dietary management of idiopathic hyperoxaluria	691
Assessment of nutritional status	631	Management of secondary hyperoxaluria	693
Nutritional requirements	635	Uric acid stones	693

# About the editors

---

**Joel D. Kopple, MD**, an editor of the book's first three editions, is Professor Emeritus of Medicine and Public Health at the David Geffen School of Medicine at UCLA and UCLA Fielding School of Public Health, Los Angeles, California, and is a member of the Division of Nephrology and Hypertension and The Lundquist Institute at Harbor-UCLA Medical Center, Torrance, California. Dr. Kopple was the Chief of the Division of Nephrology and Hypertension at Harbor-UCLA Medical Center from 1982 to 2007. He has coauthored over 600 scientific papers and book chapters and has edited or coedited 15 seminars and proceedings. Dr. Kopple is a former president of the National Kidney Foundation (NKF), the American Society of Parenteral and Enteral Nutrition, the International Society for Renal Nutrition and Metabolism, and the International Federation of Kidney Foundations and was a founder of World Kidney Day.

**Shaul G. Massry, MD**, an editor of the book's first three editions, is Professor Emeritus of Medicine and Physiology and Biophysics at the Keck School of Medicine, University of Southern California, Los Angeles, California. He served as the Chief of its Division of Nephrology from 1974 to 2000. He has published over 600 scientific papers and over 80 book chapters, and he is an editor or coeditor of 28 books. Dr. Massry has received honorary doctorates from 14 universities across Europe, including the oldest and prestigious Charles University (Prague, Czech Republic), The University of Bologna (Italy), and the University of Padua (Italy). Dr. Massry is a former president of the National Kidney Foundation (NKF).

**Kamyar Kalantar-Zadeh, MD, PhD, MPH**, an editor of the book's third edition and an Editor-in-Chief of the *Journal of Renal Nutrition*, is a professor of Medicine, Pediatrics, Public Health and Nursing Sciences, and the Chief of Nephrology, University of California Irvine School of Medicine, Irvine, California; an adjunct professor of Epidemiology, UCLA Fielding School of Public Health, Los Angeles, California; and a staff physician in Veterans Affairs Hospital, Long Beach, California. Dr. Kalantar is a former president of the International Society for Renal Nutrition and Metabolism and the International Federation of Kidney Foundations, cochair of the joint steering committee of World Kidney Day, and a Chair of the Medical Advisory Committee of the National Forum of the ESRD Networks. He has served as a PI of a dozen National Institutes of Health grants and has coauthored over 800 manuscripts in peer-reviewed journals.

**Denis Fouque, MD, PhD**, is a professor of Nephrology at the University Claude Bernard Lyon1 and the chief of the Division of Nephrology, Dialysis and Nutrition at Lyon-Sud Hospital in Lyon, France. He conducts research in nutrition and metabolism in kidney diseases and in evidence-based nephrology. He was the founder Editor of the Renal Cochrane Collaboration. He was the Research Vice-President Health Affairs at the University Claude Bernard Lyon1. He is a former President of the International Society for Renal Nutrition and Metabolism, former Editor-in-Chief of the *Journal of Renal Nutrition*, and current Editor-in-Chief of *Nephrology Dialysis Transplantation*. He has coauthored over 400 manuscripts in peer-reviewed journals and 25 book chapters.

Normal and altered metabolism of  
chronic kidney disease

# The KDOQI Clinical Practice Guidelines for Nutrition in CKD: 2020 update

*T. Alp Ikizler<sup>1</sup> and Lilian Cuppari<sup>2</sup>*

<sup>1</sup>Department of Medicine, Division of Nephrology and Hypertension, Vanderbilt University School of Medicine, Nashville, TN, United States <sup>2</sup>Oswaldo Ramos Foundation-Hrim, Federal University of Sao Paulo, Sao Paulo, Brazil

## Introduction

Clinical practice guidelines are statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options. Rather than dictating a one-size-fits-all approach to patient care, clinical practice guidelines offer an evaluation of the quality of the relevant scientific literature and an assessment of the likely benefits and harms of a treatment. This information enables health care providers to proceed accordingly, selecting the best care for a unique patient based on his or her preferences [1].

The original Clinical Practice Guidelines for Nutrition in Chronic Renal Failure by the National Kidney Foundation (NKF) Disease Outcomes Quality Initiative (KDOQI) was published in 2000 and provided in-depth information and recommendations regarding the several nutrition-related aspects of chronic kidney disease (CKD) [2]. Since then, there has been a remarkable increase in studies with focus on nutrition assessment and management of CKD. Moreover, the methodology for Clinical Guidelines development has also changed considerably. Therefore an update of the original guideline was timely and necessary. The KDOQI Clinical Practice Guideline for Nutrition in CKD: 2020 Update was developed as a joint effort by the NKF and the Academy of Nutrition and Dietetics (AND). In this chapter we will provide an overview of the process regarding guideline development and a concise description of the recommendations.

## The guideline development process

The guideline development process involved multiple groups, primarily the NKF and AND, and the select members of the International Society of Renal Nutrition and Metabolism (ISRNM) who provided a critical review of the document. A work group was formed with members chosen through an application and review process considering the expertise in the diverse fields of nutrition in CKD and with special attention to include members from different countries to have representatives from each continent. The work group members consisted of physicians, registered dietitians or nutritionists, researchers, and methodological experts.

The steps in the guideline development process included selection of topics; determination of the scope of the topic; review of the evidence for clinical recommendations; and development, review, and approval of the recommendations.

The focus of the updated guideline defined by the work group members comprised of adults aged 19 years and older, CKD stages 1 through 5, including patients on maintenance dialysis and patients with a functioning kidney transplant. Three main areas were covered: macronutrients (including nutritional assessment), micronutrients and electrolytes, and other nutrients. Given the scope of the project and need for timeliness, the literature search was restricted to studies published between 1985 and 2017. Fig. 1.1 summarizes the steps followed to conduct comprehensive systematic reviews and how the findings from the systematic reviews were used to develop the guidelines according to the Standards for Developing

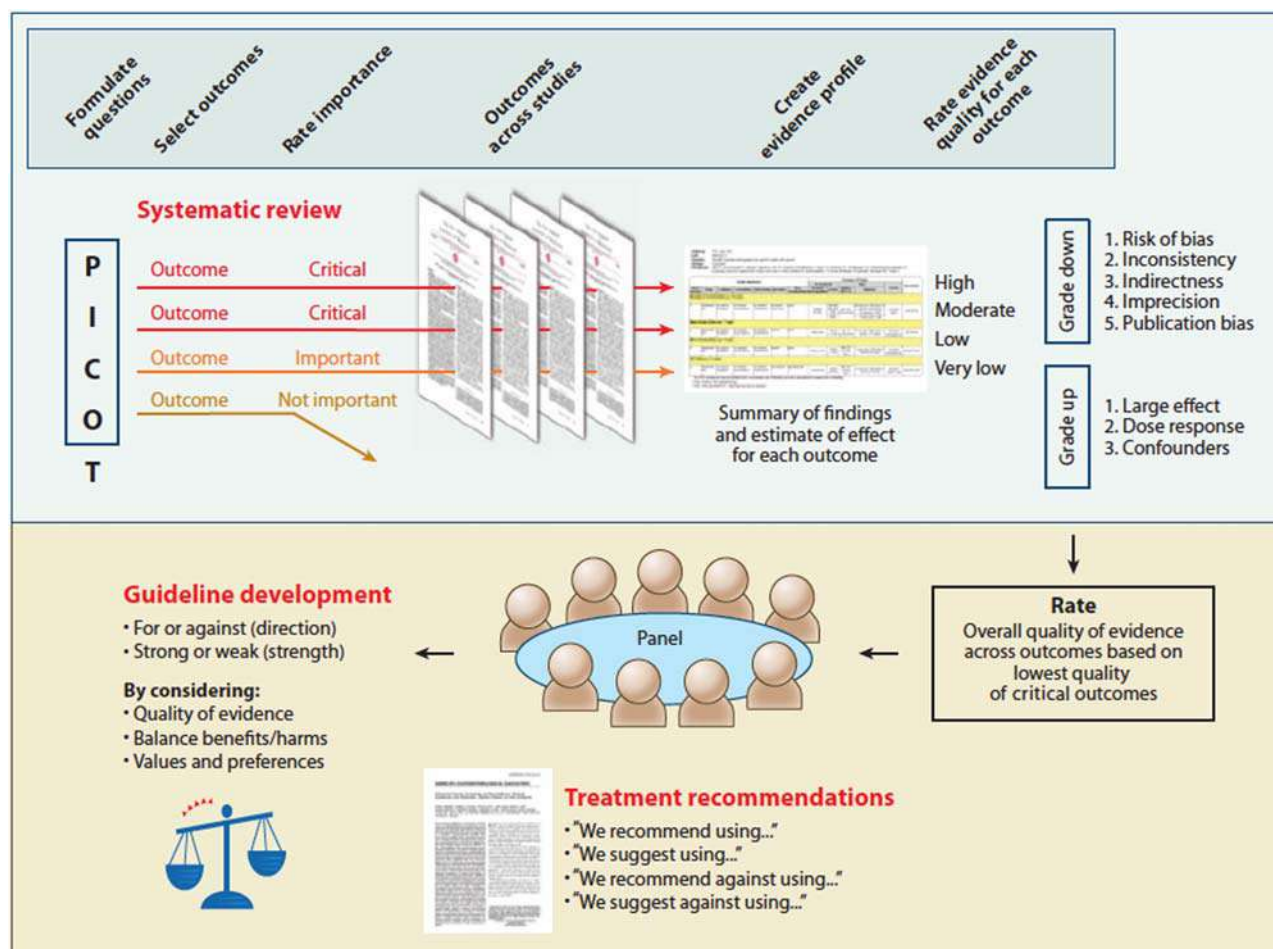

FIGURE 1.1 Schematic representation of the systematic review steps to inform guideline development panels. Reprinted with permission from Falck-Ytter Y, Schünemann H. Trustworthy Clinical Practice Guidelines as stated by the National Academy of Medicine [1].

Approximately 100 questions covering both assessment and intervention of the three subtopics were proposed by the work group. The key questions used for evidence review are listed in the Guideline document [3]. For assessment questions, only studies that tested the validity, reliability, or relationship of an assessment tool against a comparative tool or mortality were included in the review. For intervention questions, only randomized controlled trials with a comparator and which had at least six individuals per arm were included. The main outcomes defined were mortality, comorbid conditions, CKD progression, quality of life, nutritional parameters, and nutrient biomarkers.

The first literature search focused on assessment and intervention questions identified 4857 and 11,017 potential studies, respectively. After applying the inclusion and exclusion criteria, 125 studies met the inclusion criteria for assessment questions and 225 studies met

the criteria for the intervention questions. Relevant data were extracted from the included articles using a standardized data extraction tool. All included studies were critically appraised for risk of bias. Descriptive synthesis of evidence was conducted for all identified outcomes for which there were included studies. The review results were then provided for the work group members in three formats: (1) evidence summary, (2) study characteristics, and (3) quality of evidence. Each of the conclusion statements was assigned a GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) to reflect the quality of studies, inconsistency of results, imprecision, indirectness of the evidence, and publication bias [4]. Using this method, the evidence for each outcome of interest was graded as A (high), B (moderate), C (low), or D (very low). The work group members then translated the available evidence into action statements and rated the strength of the recommendation. The grade for strength of recommendation was assigned Level 1 or Level 2.

guideline the current guideline provides a substantial incremental value in the topics that are covered.

The recommendations for nutrition assessment have been greatly expanded including new methods and tools to assess nutrition status and body composition, such as bioelectrical impedance, handgrip strength, conicity index, malnutrition inflammation score, and methods to measure or to estimate energy expenditure. Together with the recommendations on traditional anthropometric parameters, a detailed discussion concerning the accuracy, validity, and limitations of each method and tool is provided to support practitioners with their appropriate use in multiple scenarios. The need for further research in this area is critically important, especially in terms of development of risk prediction models using multiple nutritional markers, determining the effects of various nutritional interventions on nutritional markers, and whether changes in values of a nutritional marker correlate with outcomes as a marker of efficacy.

A new topic included in the 2020 guideline is the recommendation for MNT [5]. The recommendation emphasizes the importance of providing this collaborative approach by the health care team to optimize the nutritional care by tailoring it to the individuals' needs, nutritional status, and comorbid conditions.

Due to the expansion of well-designed studies on the impact of dietary protein intake on various outcomes in patients with CKD over the last two decades [6], a high level of evidence for recommendations for dietary protein intake has been achieved. More specifically, the updated guidelines provide recommendations for protein restriction (with or without ketoacid analogs) in appropriate patients with CKD to reduce the risk of initiation of renal replacement therapy and death. It is noted, however, that there is a significant need for future appropriately designed clinical trials to investigate the effects of very low protein diets and protein type (vegetable vs animal) on important CKD-related clinical outcomes.

In recent years, emerging evidence has indicated that overall eating patterns, instead of individual nutrients, maybe a better predictor of outcomes in CKD [7,8]. Recommendations regarding the Mediterranean diet and a dietary pattern with increased intake of fruits and vegetables are discussed in the guidelines and the need for future studies to examine their potential impact is further highlighted.

Protein-energy wasting (PEW) is still highly prevalent in advanced CKD patients, and treatment of this condition continues to be challenging for the health care team [3,9,10]. Detailed and comprehensive recommendations addressing different types and routes of nutritional supplementation in the face of PEW are provided in the newly updated guidelines. Notably, strategies to

prevent dialysis-induced catabolism and interventions to treat PEW in patients with CKD stages 3–5 and maintenance dialysis patients are presented in detail. Nevertheless, several important considerations regarding prevention and treatment of PEW, such as who to treat (all patients vs the higher risk individuals), when to administer supplements (e.g., immediately before or during dialysis treatments vs during the interdialytic interval), how much and for how long to administer, and how to monitor the response are not covered by the current guidelines and require further research.

The inclusion of micronutrient (vitamins and trace elements) recommendations represents an important advance in the updated guidelines. However, provision of accurate and reliable evidence-based statements for assessment and administration of micronutrients in patients with CKD remains challenging. Despite the large number of trials on the effects of micronutrients supplementation, most of them do not report the baseline status of the micronutrients examined or the dietary intake during the studies; this has led to significant limitations in the evidence-based recommendations. Furthermore, differences in published studies regarding the doses of the supplements, duration of the intervention and the outcomes analyzed, among several other issues, make it difficult to provide recommendations on the amounts of micronutrients to be given and the types of CKD patients who should receive these supplements. Taking all these issues into consideration, the work group agreed to develop opinion-based recommendation to guide practitioners and to emphasize the need to individualize micronutrient supplementation.

The last set of guidelines is dedicated to electrolyte recommendations. It is well known that as CKD progresses and develops, disturbances in mineral metabolism and changes in acid–base homeostasis occur [11]. Therefore dietary control of electrolytes and net acid production are of paramount importance for the prevention and treatment of many of the complications of CKD. Although the level of evidence is still low, a statement on management of net acid production through increased intake of fruits and vegetables and its potential effect on reducing the decline of kidney function are provided along with detailed suggestions for future research. Regarding dietary phosphorus, besides the evidence for recommending adjustment in phosphorus intake to maintain normal serum phosphorus concentrations, the importance of recognizing the bioavailability of dietary phosphorus sources, with emphasis on phosphorus additives, is addressed. The guidelines also provide recommendations on dietary sodium and potassium intake based on the available evidence. Most importantly, the guidelines do not provide any recommendations related

to pharmaceutical therapies for any of the electrolytes, since this was beyond the scope of the project.

## Conclusion

The updated nutrition guidelines in CKD is a result of more than 5 years of work of multiple individuals and provides substantial information based on recent advancements in the care of patients with CKD. It is important to point out, however, that the guideline statements do not cover certain patient populations such as those who are obese, elderly, who have acute kidney injury. Nor do the guidelines address such interventions as exercise or any pharmacotherapies to prevent or treat nutritional abnormalities. The guidelines also do not stratify patients based on their ethnic or racial backgrounds, which could have obvious implications. Since the guideline updates are a continuous and dynamic process, these additional areas, with their significant clinical relevance, will be covered in the future.

## Introduction

Chronic kidney disease (CKD) is a progressive disorder that afflicts 15% of the US adults or over 30 million individuals [1]. The presence of CKD is characterized by metabolic abnormalities that result from the progressive accumulation of unexcreted toxins as kidney excretory capacity declines. As these metabolic processes worsen, patients develop the uremic syndrome, which is characterized by fatigue, loss of lean body mass, and a multitude of nonspecific symptoms. It is speculated that these nonspecific, uremic symptoms are generated by the accumulation of uremic toxins and these, in turn, are produced by the metabolism of protein and ultimately, amino acids. As kidney function is lost, increasingly severe uremic symptoms develop in association with the progressive accumulation of potential uremic toxins, such as, *p*-cresol, indoxyl sulfate, and products of the digestion of indoles. However, the assignment of specific uremic symptoms to the accumulation of a specific uremic toxin or group of toxins has not been accomplished. Instead, the circulating levels of uremic toxins in patients with CKD are associated with the development of inflammation, inhibition of wound repair, and the generation of cardiovascular disease in patients with CKD [2].

By far, the body's largest store of protein and amino acids is muscle, and it participates in the development of uremic symptoms because muscle protein can be degraded to amino acids and its metabolites. The characterization of protein turnover and of losses of muscle proteins was developed in large part by Rittenberg and Urey in 1939 [3]. They succeeded in generating a

radioisotope of nitrogen (15N). Subsequently, Schoenheimer et al. reported that following the administration of 15N-labeled tyrosine to animals, only half of the label was excreted [4]. The rest of the label was incorporated into body proteins, confirming that proteins are in a dynamic state of synthesis and degradation. Reports of muscle turnover rates in humans revealed that adults degrade and synthesize roughly 3%–5% of the total amount of cellular proteins daily and that this process is highly selective. For example, in CKD there is impairment in intracellular signaling responses to insulin or insulin-like growth factor-I (IGF-I) resulting in muscle atrophy. There also are enhanced potential mediators of the processes of protein synthesis and degradation. For example, metabolic acidosis and increases in circulating angiotensin II or inflammatory cytokines levels can contribute to muscle wasting by stimulating the degradation of muscle proteins by the ubiquitin–proteasome pathway (UPS) [5,6]. It is well established that this is the major proteolytic system that degrades proteins in normal individuals and in patients with CKD [7]. Besides regulating protein turnover, muscle influences the intracellular stores of amino acids and specifically, the turnover of branched-chain amino acids (BCAA). This is relevant because BCAA are critical “building blocks” of muscle protein. Not surprisingly, certain factors that regulate muscle protein metabolism also regulate the turnover of BCAA. The development of metabolic acidosis activates the UPS to degrade muscle protein and at the same time, it activates branched-chain ketoacid dehydrogenase to degrade BCAA. Thus muscle metabolism is integrated with amino acid metabolism [8–10]. In this chapter, we will explore the roles of other

mediators, including metabolic responses to myostatin, a negative regulator of muscle mass, and a critical mediator of muscle metabolic defects in CKD [11]. We address these responses because they provide insights into the pathophysiology of nutritional problems raised by CKD. Moreover, in patients with progressive CKD, attention to the evaluation and correction of nutritional factors can substantially ameliorate specific metabolic problems, including maintenance of protein stores and slowing of the loss of residual kidney function (i.e., progression of CKD). In this chapter, we will illustrate mechanisms that regulate the degradation of muscle proteins to peptides and amino acids and we will discuss how changes in protein metabolism influence the formation of metabolic disease and uremic toxicity.

Before reviewing changes in protein and amino acid turnover, we will briefly discuss factors that influence the development of uremia. First, the “intact nephron hypothesis” explains why monitoring the glomerular filtration rate (GFR) is necessary. The hypothesis deals with the finding that each kidney is composed of 0.75–1.25 million nephrons, and each of these nephrons functions as an independent unit [12,13]. The sum of remaining healthy nephrons in damaged kidneys provides a residual, “whole-kidney” GFR. Therefore the GFR of the damaged kidney provides a means of gauging the remaining physiologic and metabolic functions of the kidney (e.g., regulation of blood pressure and endocrine functions plus the concentrations of ions and the accumulation of unexcreted or undegraded metabolic waste products). In patients with diabetic nephropathy or other kidney diseases, the rate of decline in GFR is generally linear and hence can be measured as the rate of loss of kidney function if plotted as the reciprocal of serum creatinine or GFR estimated from serum creatinine or cystatin (eGFR). The relationship is linear in most patients without breakpoints related to acute kidney injury, providing an index of the rate of loss of whole-kidney GFR [14].

### Influence of protein intake on CKD

In the first half of the 20th century, Thomas Addis introduced the concept of “osmotic work” [15]: rodents were fed diets containing varying amounts of protein, and those fed a high-protein diet developed renal hypertrophy and evidenced kidney damage and ultimately death. Although the contribution of an increased osmotic workload to progressive kidney damage has not been documented, subsequent investigators have determined that dietary protein loading resulted in increases in GFR and glomerular

hypertension and ultimately induced progressive glomerulosclerosis.

Understanding how changes in protein metabolism influence uremic toxicity is important because once activated, mechanisms that create uremic toxins are not easily corrected. A potential intervention that slows the loss of kidney function in patients with CKD is to limit the amount of protein in the diet [16,17]. This strategy can effectively suppress uremic toxicity by at least three mechanisms: (1) nitrogen-containing uremic toxins and organic acids are derived from the catabolism of dietary and endogenous proteins. Consequently, the more protein in the diet, the greater amounts of amino acids that are available for the production of uremic toxins. (2) There is increasing evidence that the production of uremic toxins arises by the gastrointestinal microbiome leading to the ongoing loss of kidney function. For example, increasing dietary protein intake provides more substrates for the synthesis of uremic toxins in the intestinal microbiota. (3) Dietary manipulation to decrease the accumulation of uremic toxins is not limited to limiting dietary protein alone since diets that are rich in protein also contain an excess of potentially toxic inorganic ions, including sodium, phosphate, potassium, and hydrogen ion [18–20]. For example, increasing dietary protein intake can enhance the metabolism of amino acids and the degradation of some of these amino acids (e.g., sulfa-containing amino acids and ring-shaped amino acids, phenylalanine, tyrosine, and tryptophan metabolism leads to an increase in the production of acid that is poorly excreted because of the loss of kidney functions). In addition, increases in acid levels can stimulate muscle protein losses and increase the progression of muscle wasting.

### Dietary restriction of protein

The original approach for determining specific metabolic targets was to examine the effect of changes in dietary protein and to measure nitrogen balance. The approach is used because it is a precise measure of the net balance between protein synthesis and protein degradation. Notably, the World Health Organization and nutrition researchers have used it for more than 80 years dietary protein and amino acid requirements [21]. The minimum amount of high biological value protein intake within which protein homeostasis could be maintained is 0.36 g/kg per day, a level of protein intake that requires substantial metabolic adaptation to utilize the dietary protein maximally. However, a dietary level of 0.6 g/kg per day and the modification of the diet to increase the intake of primarily high biological value protein; using this level of dietary protein,

TABLE 2.1 Notable dietary protein restriction studies.

CKD, Chronic kidney disease.

RCT, Randomized control trial.

that contributes to the development of uremic bone disease [47,48]. The specific concept was that increasing CKD led to the retention of more acid and this, in

turn, worsened the degree of abnormal metabolic responses. Their reports provided at least two factors related to the acidosis that would contribute to the

development of the bone disease: (1) an increase in the amount of dietary protein generates more acid; and the degree of renal insufficiency limits the excretion of acid arising from metabolism of proteins and amino acids. It was concluded that an excess in dietary protein increases the intake of sulfur-containing amino acids plus phosphorylated proteins and lipids. These substrates are metabolized to sulfuric and phosphoric acids and when CKD limits the excretion of acid which is by bicarbonates, intracellular buffers, and bone. Although these processes ameliorate the acidemia, the trade-off principle is that these patients develop more bone disease. These considerations can have clinical benefits. As an example, results from a randomized, controlled trial of oral bicarbonate therapy in chronic ambulatory peritoneal dialysis patients identified an increase in body weight and muscle mass plus fewer hospitalizations compared to patients who had higher alkali concentrations in their dialysate. [49]. Several other investigations have linked the development of

acidosis to protein degradation and demonstrated the salutary effects of correcting acidosis in otherwise normal and CKD patients (Table 2.2) [28,49–60].

Not only does the successful treatment of metabolic acidosis suppress losses of protein mass in patients with CKD but it also has been reported that correcting acidosis can even slow the rate of loss of kidney function [55,61,62]. Besides these positive responses, treatment of metabolic acidosis can also suppress renal injury by blocking the tubulointerstitial inflammation arising from excess acid plus ammonia production with activation of complement and endothelin.

Evidence indicates that the metabolism of amino acids and proteins in the muscle is linked. For example, in skeletal muscles of rodent models of metabolic acidosis, there are parallel changes in the catabolism of protein and amino acids. These changes act in parallel because stimuli like metabolic acidosis stimulate muscle protein degradation by activating the UPS by complicated pathways that include stimulation of genetic

TABLE 2.2 Evidence that metabolic acidosis induces protein catabolism in children and CKD patients.

Subjects investigated	Measurements of effectiveness	Outcome of trial
Infants [32]	Low birth weight, acidotic infants were given $\text{NaHCO}_3$ or $\text{NaCl}$	$\text{NaHCO}_3$ supplement improved growth
Children [33] with chronic kidney disease (CKD)	Children with CKD had protein degradation measured	Protein loss was ~ twofold higher when $\text{HCO}_3^-$ was $< 16$ mM compared to $> 22.6$ mM
Normal adults [34]	Induced acidosis and measured amino acid and protein metabolism	Acidosis increased amino acid and protein degradation
Normal adults [35]	Induced acidosis and measured nitrogen balance and albumin synthesis	Acidosis induced negative nitrogen balance and suppressed albumin synthesis
CKD [36]	Nitrogen balance before and after treatment of acidosis	$\text{NaHCO}_3$ improved nitrogen balance
CKD [37]	Two years $\text{NaHCO}_3$ therapy versus standard care	Slowed loss of creatinine clearance and improved nutritional status
CKD [38]	Essential amino acid and protein degradation before and after treatment of acidosis	$\text{NaHCO}_3$ suppressed amino acid and protein degradation
CKD [39]	Muscle protein degradation and degree of acidosis	Proteolysis was proportional to acidosis and blood cortisol
CKD [40]	Nitrogen balance before and after treatment of acidosis	$\text{NaHCO}_3$ reduced urea production and nitrogen balance

CAPD, chronic ambulatory peritoneal dialysis.

components of the UPS [5–52]. In addition, Garibotto et al. have reported that intestinal BCAA absorption occurring after a meal involves nonessential amino acids and branched-chain ketoacid dehydrogenase [9,63]. The result leads to excessive catabolism of BCAA [10]. From these reports, we conclude that several factors, including metabolic acidosis, stimulate mechanisms of amino acid and protein degradation [64–66]. Interestingly, there also is a role for glucocorticoids in mediating muscle protein catabolism: it has been demonstrated that metabolic acidosis stimulates muscle protein breakdown only if there is a physiologic increase in glucocorticoid production [64,67].

Raising the amount of protein in the diet of patients with CKD will increase the intake of sulfa-containing amino acids (e.g., methionine, cysteine, and cysteine) as well as the intake of other acid amino acids and such as arginine, phosphoproteins, and phospholipids. Metabolism of these amino acids and phosphorylated compounds will generate acid, and when acid production exceeds the ability to excrete the acid, hydrogen ion exacerbates the complications of metabolic acidosis. This is easily detected by measuring the serum bicarbonate in patients with CKD: if the clearance is stable and the serum bicarbonate level is <22 mM, dietary protein is likely to be the culprit and dietary protein restriction should be curtailed [68]. There are at least two other methods used to treat metabolic acidosis of CKD: (1) by increasing the amounts of fruits and vegetables in the diet to raise the intake of citrate to neutralize acid accumulation and (2) by administering  $\text{NaHCO}_3$  or solutions of sodium citrate and citric acid [56,69].

### Role of protein metabolism in hypertension

Estimates of the prevalence of stage 2 hypertension (>140/90mmHg) in patients with CKD exceed 60% [70]. Protein intake and metabolism are among factors that influence blood pressure by its association with the elasticity of blood vessel walls. In addition, patients with CKD are at increased risk for developing positive sodium balance. If CKD patients eat an excess amount of protein, they also will ingest ions and ion precursors. When the amounts of salt and other ions in the diet exceed the kidney's capacity to excrete them, the retention of inorganic ions will contribute to the development of hypertension.

Arginine has the potential to influence many physiologic processes because it is a major substrate for the synthesis of nitric oxide. For example, L-arginine supplements prevent the development of hypertensive nephrosclerosis in salt-sensitive Dahl/Rapp strain of rats [71,72]. In animal models of diabetic nephropathy, L-

arginine supplements were found to ameliorate the degree of nephropathy and reduce the renal hypertrophy that is induced by a high-protein diet [73]. Finally, arginine supplements have improved renal function in rats with ureteral obstruction or puromycin aminonucleoside-induced nephrosis [74]. A long-standing stumbling block to the interpretation of these responses is the problem of the arginine paradox: it states that the beneficial effects of arginine supplements occur even though the intracellular arginine concentration is substantially above the Michaelis constant of nitric oxide synthase. Erez et al. found that intracellular nitric oxide synthase forms a complex with argininosuccinyl lyase providing L-arginine as a substrate for nitric oxide synthase [75]. In healthy subjects, oral or intravenous administration of L-arginine causes diuresis and lowers blood pressure but changes GFR minimally; these changes can be associated with the development of microalbuminuria [76–79]. Taken together, dietary arginine could raise diuretic responses in fluid overload states, although this has not been rigorously tested. Caveats to the use of L-arginine are that in children with CKD, administration of arginine does not improve endothelial function [80].

### Uremic toxins derived from protein metabolism

Pathophysiologic responses to ions that are associated with protein intakes >1.2 g protein/kg/day develop a constellation of problems in patients with CKD and uremia [81] (see Chapter 6: Uremic Toxins: An Integrated Overview of Classification and Pathobiology). There are at least three principal mechanisms of protein and amino acid metabolism that generate uremic toxicity. First, catabolism of dietary proteins, peptides, and amino acids occurs when proteases, amino acid oxidases, and gut bacteria degrade protein and amino acids. Second, metabolic processes mediated by gut bacteria can activate primary or secondary changes during the metabolism of protein, peptides, and amino acids [82]. In patients with CKD, the microbiome is altered by dietary factors as well as by impaired protein synthesis, frequent exposure to antibiotics, use of iron and phosphate binders. Many uremic toxins are produced by the fermentation of protein and amino acids by dysbiotic bacteria and are absorbed into circulation. The toxic compounds produced from protein metabolism include ammonia, thiols, phenols, indoles, and other solutes, and these changes could contribute to uremic symptoms (see Chapter 6: Uremic Toxins: An Integrated Overview of Classification and Pathobiology). Third, indirect pathways can produce toxic products from the metabolism of proteins, peptides, and amino acids that

enter into the gut. Products of protein fermentation substrates in the gut can influence metabolic pathways, including insulin resistance and inflammation [83–86]. Although investigations into experimental and clinical consequences of metabolic changes caused by variations in the gastrointestinal microbiome have been partially defined, additional investigations are needed to document their role in the metabolism of protein and amino acids.

Examples of uremic toxins include *p*-cresol arising from the metabolism of phenol and indoxyl sulfate, a product of tryptophan metabolism. In patients with CKD, circulating levels of these tryptophan-derived compounds are associated with the presence of inflammation, the inhibition of wound repair, and abnormalities in vascular diseases [2]. Specifically, increased circulating levels of indoxyl sulfate or *p*-cresyl sulfate have been linked to CKD progression and cardiovascular morbidity and mortality [87–89]. The contribution of these compounds to uremic toxicity was formally tested by oral administration of a carbon adsorbent of indoxyl sulfate, AST-120, which is capable of blocking its absorption from the gastrointestinal tract. Several rodent-based studies have shown that AST-120 can slow down the CKD progression and improve the metabolism of CKD models. However, a large clinical trial conducted in the United States did not support the beneficial responses to treatment with AST-120 [90–92].

Homocysteine is an example of an amino acid metabolite of methionine. In adults without CKD, homocysteine has been linked to the acceleration of the development of atherosclerosis, and potentially an elevated homocysteine level may portend a poor prognosis in patients with coronary artery disease [93,94]. In CKD patients circulating homocysteine is found at high levels, but the mechanism for this result is unknown [95]. Presumably, high circulating levels of homocysteine arise from abnormalities in the metabolism of sulfur amino acids in CKD patients, but the biochemistry of impaired metabolism of sulfur-containing amino acids is unknown [96]. In healthy adults, the treatment for accelerated atherosclerosis occurring in association with a high homocysteine level is vitamin B6 plus folinic acid, but this therapy has not shown a clinically significant reduction in cardiovascular outcomes in CKD patients [97].

## Excessive sodium

Salt is ubiquitous and is widely used, especially in the modern era, and has become a food preservative dedicated to enhance culinary flavor. Importantly, its consumption is correlated with protein intake. For

patients with CKD, sodium chloride develops a critical metabolic response that is generated when kidney function is impaired. In dealing with salt intake, the trade-off hypothesis mentioned before is relevant. It refers to a CKD-stimulated activation of pathophysiological responses that interfere with kidney functions. For example, patients with CKD initially develop sodium retention, which results in expansion of the extracellular volume and increases in body weight and blood pressure. These stimuli, however, trigger pathophysiological adaptations in the remaining tubules that impair tubular reabsorption of sodium. In this case, the trade-off for the CKD patient is the persistence of impaired tubular sodium reabsorption. For CKD patients, this response can create difficulties when there is an abrupt decrease in their salt intake. For example, if CKD patients who are in the steady state develop a sharp decrease in salt intake, the response of their kidneys will include a sluggish increase in their ability to raise the tubular reabsorption of sodium. The consequence will result in a net loss of sodium of both extracellular and intravascular volumes causing reduced perfusion of the kidneys and subsequently, a decrease in GFR [98]. On the other hand, a long-term decrease in salt intake appears to have beneficial effects on renal progression [99].

Proteinuria is a determinative factor in the progression of renal disease. High sodium intake in experimental models is associated with increased proteinuria and GFR decline. Furthermore, there is evidence that a high or even normal sodium intake may counteract the anti-proteinuric effects of angiotensin-converting enzyme inhibitors (ACEi). Notably, in a reanalysis of the Ramipril Efficacy In Nephropathy (REIN) and REIN-2 trials, a high dietary sodium blunted the antiproteinuric impact of ACEi, an effect that is independent of blood pressure control [100]. An excessive sodium intake during the progression of CKD increases extracellular volume and contributes not only to elevated blood pressure, proteinuria, and progressive renal disease but also exacerbates cardiovascular disease [101]. Although not traditionally thought of as a uremic solute, salt should meet the criteria for one because it accumulates in CKD and is toxic in high amounts [102].

## Phosphates

Phosphate meets the criteria for a uremic toxin because it accumulates in CKD and is toxic at high levels. The nature and degree of toxicity with phosphates are varied. Phosphates are minerals present in bone and are involved in a host of cellular processes. Specifically, organic phosphates are found in high amounts in protein sources—all meats, dairy products,

and plant-based food such as beans and nuts. Moreover, they are frequently added to food as a preservative with high amounts present in packaged foods and many “dark” beverages. A report by Williams et al. revealed that dietary protein restriction will significantly decrease the urinary excretion of phosphates and others have reported that dietary protein restriction in advanced CKD is associated with lower requirements for phosphate binders [26,103].

In animal models of CKD, it has been shown that phosphate loading increased the rate of loss of kidney function (i.e., increased progression). Conversely, dietary phosphate restriction has been linked to responses that include prevention of proteinuria, kidney calcifications, histologic changes, functional deterioration, and death. Some of these findings were also observed in patients with CKD that were treated with low-phosphate diets. In contrast, diets with higher amounts of phosphate were associated with increases in the progression of CKD. In the REIN and REIN-2 cohorts, patients with higher serum phosphorus levels were associated with an incremental risk of progression or development of end-stage renal disease (ESRD). Interestingly, the investigators also found that elevated phosphate levels were associated with blunting of the renoprotective effects of the ACEi used [104]. A proposed mechanism for this blunting is that phosphate becomes a potent stimulus for fibroblast growth factor-23 (FGF-23) secretion. Stimulation of the FGF receptor common to all members of the FGF family increases the production of the ACE, which may activate the renin-angiotensin-aldosterone axis but undermines the effect of ACEi and contributes to the progression of CKD.

A high phosphate intake, especially in CKD patients who have high circulating levels of phosphates, promotes vascular calcification, a significant contributor to cardiovascular morbidity and mortality. Elevated phosphate levels induce vascular smooth muscle cells to undergo transformation into osteochondrogenic cells which produce bone matrix (apatite) just like osteocytes [105,106]. This pathologic adaptation can develop into deadly consequences by increasing coronary artery disease, stroke, and peripheral arterial disease. In patients with advanced CKD, medial arterial calcification can result in a necrotizing skin condition called calcific uremic arteriolopathy or calciphylaxis [107].

### **Dysregulation of proteolytic pathways in CKD**

Proteins in all tissues are continually “turning over” (i.e., being degraded and replaced by new synthesis). The magnitude of the dynamic processes of protein

synthesis and protein degradation is not small. Estimates of protein turnover indicate that normal adults degrade and resynthesize roughly 3%–5% of body proteins daily, and this occurs at measured rates of 3.5–4.5 g protein/kg/day [7,108–110]. This rate of protein metabolism is equivalent to breaking down and rebuilding 1–1.5 kg of muscle/day (based on the assumption that 20% of muscle weight is protein). From this perspective, processes of protein breakdown must be highly selective, otherwise, degraded protein would be irreversibly lost. Notably, the selectivity of protein degradation is not achieved by a mechanism based on a specific protease degrading specific proteins. Instead, different conditions or stimuli result in the activation of specific proteases that degrade proteins that have been identified for degradation.

In patients or models of CKD, there is an imbalance between protein synthesis and degradation, resulting in a net loss of protein stores. This loss of protein stores contributes to the morbidity and mortality that develops in CKD. For example, epidemiological and clinical reports document that muscle protein catabolism increases the risk of morbidity and mortality in CKD as it does in other catabolic conditions (e.g., heart failure, cancer, and aging) [111–113]. Specific contractile proteins lost from muscle account for about two-thirds of proteins in muscle and their loss is mainly responsible for the weakness and disability of patients who experience muscle wasting. Moreover, cross-sectional analyses indicate that muscle wasting is frequent and is detected in 40%–70% of patients with ESRD [114]. Besides the loss of body weight (principally, loss of muscle mass), there is a progressive reduction in the proteins that regulate metabolism and cellular renewal. Unfortunately, muscle protein wasting in patients with CKD is underappreciated and slowly progressive in many patients.

At least four major proteolytic pathways contribute to the loss of muscle protein in CKD. The pathways are lysosome-mediated protein degradation; intracellular proteolysis by calcium-activated proteases (calpains); ATP-dependent proteases (the UPS is the dominant process in this category); and poorly understood proteases that do not require energy for the losses of cellular proteins [7].

### **The ubiquitin–proteasome system**

In all cells, including muscle, the UPS is the primary proteolytic system that degrades proteins. There is abundant evidence that CKD and its complications stimulate the UPS to breakdown proteins in muscle and other organs. Evidence for the primacy of the UPS is that enhanced protein degradation in isolated

muscles of rodents with CKD is blocked by treatment with inhibitors of the proteasome [5,115]. There also is evidence that transcription of a similar set of genes when protein degradation arises in different models of muscle wasting (e.g., CKD, diabetes, starvation, and cancer) [116,117]. Since a large amount of proteins is being degraded each day and since these processes not only affect the regulation of cell processes but also affect the regulation of metabolic pathways, the specificity of the UPS must be exquisite. The selective degradation of different proteins is determined mainly by the cell's content of two E3 ubiquitin ligases, atrogin-1/MAFbx, and MuRF-1 [118]. The expression of these enzymes in muscle is correlated with the rate of muscle protein degradation.

The UPS initiates two multistep biochemical reactions: first, it "tags" proteins destined for degradation by conjugating them to ubiquitin (Ub), a member of the heat-shock protein family (Fig. 2.1). Secondly, the Ub-tagged protein is degraded by the 26S proteasome [119]. The process of Ub conjugation begins with the ATP-dependent activation of Ub by a single E1 isoform (Ub-activating enzyme). The activated Ub then interacts with one of 20–40 isoforms of the E2 Ub-carrier proteins, providing a degree of specificity to the identification of proteins to be degraded. An E2 Ub-carrier protein interacts with only a limited variety of substrate proteins. E3 ubiquitin ligases catalyze a more restrictive reaction. There are more than 1000 of these E3 Ub ligases, and each recognizes only a specific protein substrate (or class of proteins). Thus a specific E3 Ub ligase is activated only when it recognizes the protein to be degraded and transfers Ub to lysines in the substrate protein. The latter reaction is repeated until

activated Ubs are transferred to form a chain of 4–5 Ub's that are attached to the target protein. This Ub chain can then be recognized by the 26S proteasome, a very large organelle consisting of >60 proteins that are organized into two particles, the 20S, barrel-shaped particle and 19S regulatory particles present at either or both ends of the 20S particle. Both particles have distinct activities. The 19S particle is capable of recognizing the polyubiquitin chain. In the presence of ATP, the 19S particle cleaves Ubs from the substrate protein so they can presumably be recycled. Also, the 19S particle unfolds the protein and translocates it into the 20S particle where it is degraded to peptides. The peptides are converted to amino acids by cytosolic peptidases. The importance of these reactions is underscored by the awarding of the 2004 Nobel Prize in Chemistry to Avram Hershko, Aaron Ciechanover, and Irwin Rose as discoverers of Ub and its biochemical role in protein degradation.

Both the conjugation of Ub to substrate proteins and the degradation of Ub-conjugated proteins are accelerated in muscle-wasting conditions. Considering the multiple steps required for the conjugation of Ub to a substrate protein and its degradation, it is not surprising that there is increased expression of key contributors to this process in muscle. These participants are recognized by increases in mRNAs of the components, including Ub, subunits of the 26S proteasomes, and two E3 Ub ligases, Atrogin-1 (also known as MAFbx) and MuRF-1. These E3 Ub ligases are critical for the breakdown of muscle proteins, and their expression increases dramatically (8- to 20-fold) in rodent models of muscle-wasting conditions [6,120–122]. In cultured muscle cells, the content of Atrogin-1 mRNA correlates closely with rates of protein breakdown, providing

FIGURE 2.1 Various proteins including muscle are marked for proteasomal degradation by being linked to the polypeptide co-factor, ubiquitin. evidence of their importance. In patients, increased levels of mRNAs encoding Ub or subunits of the proteasome provide evidence for UPS activity in muscles of patients with trauma, cancer, CKD, or sepsis [123,124].

Understanding how Atrogin-1 and MuRF1 are activated is essential for understanding the regulation of protein metabolism. Two factors have been identified: the forkhead transcription factors (FoxO), and the inflammation-associated transcription factor (NF $\kappa$ B). To date, it is established that in conditions associated with impairment in insulin and IGF-1 signaling pathways such as CKD, diabetes, excess angiotensin II, and inflammation, there is enhanced activation of FoxO transcription factors. These responses result from decreased phosphorylation of FoxOs. Specifically, dephosphorylated FoxOs will translocate to the nucleus and increase the transcription of Atrogin-1 (and other genes). Alternatively, in response to inflammation, there is an activation of NF $\kappa$ B, which translocates to the nucleus to increase the transcription of the MuRF1, E3 Ub ligase, and mediators of inflammation [125,126].

In response to the progressive loss of kidney function, muscle protein synthesis decreases somewhat but the more prominent response is stimulation of protein degradation in muscle [127]. In addition to the critical role of the UPS, there is the participation of other proteases in causing muscle atrophy. The involvement of other proteases is necessary because the UPS readily degrades individual proteins in muscle, including actin, myosin, troponin, or tropomyosin, and it exhibits only limited proteolytic activity in degrading proteins present in complexes of proteins. This means that other proteases must initially cleave the muscle proteins that are present in complexes to produce substrates for the UPS [128]. In certain conditions including diabetes, excess angiotensin II, and inflammation plus CKD, we have found that the protease that performs this initial cleavage of proteins is caspase-3. These findings emphasize how CKD stimulates muscle proteolysis by activating a coordinated, multistep process. Specifically, a two-stage process is stimulated by specific signals (e.g., impaired insulin/IGF-1 signaling pathways, glucocorticoids, increasing degrees of inflammation) causing muscle wasting. First, there is an activation of the UPS and caspase-3. The latter performs an initial cleavage of the complex structure of actomyosin and myofibrils producing substrates for the UPS. Second, there is an increase in levels of mRNAs encoding specific components of the UPS. Using mRNA expression as an index of muscle wasting, it has been demonstrated that accelerated muscle wasting in CKD involves cellular mechanisms that are similar to those that cause muscle wasting in other catabolic conditions (e.g., cancer

cachexia, starvation, insulin deficiency or resistance, and sepsis) [129]. These results indicate that there is a common transcriptional program that changes in a coordinated fashion to cause loss of muscle protein and, hence, muscle mass.

The role of caspase-3 was initially uncovered in cultured muscle cells when it was found that activated caspase-3 cleaves actomyosin, producing protein fragments that are rapidly degraded by the UPS. The role of caspase-3 extends beyond experimental rodent models of catabolic conditions. Specifically, the proteolytic action of caspase-3 leaves a "footprint," a 14-kD C-terminal fragment of actin. The 14-kD actin fragment was most easily detected in the insoluble fraction of muscle; it was rarely present in the soluble fraction of muscle, presumably because the UPS rapidly degrades the 14-kD actin fragment. For example, the 14-kD actin fragment was found to be increased in skeletal muscle biopsies of patients with CKD or following burn injury or with severe osteoarthritis and muscle wasting. Regarding the influence of kidney disease, chronic hemodialysis patients were studied before and again after many weeks of exercise training. Compared to values in muscles of healthy adults, the 14-kD actin fragment was increased in muscles of hemodialysis patients but fell when the patients underwent exercise training [130].

Besides stimulation of metabolic pathways, we found that the participation of the increase in caspase-3 activity influences the activity of proteasome-mediated proteolysis in muscle. This response was linked to cleavage of specific subunits of the 19S particle of the proteasome suggesting that alteration of the specific subunits "opens" the entrance to the 20S proteasome, permitting substrate proteins to enter the proteasome where they are degraded [131]. These results, in addition to results from patients who had muscle atrophy following a burn injury, suggest that this actin fragment might potentially serve as a useful biomarker of accelerated muscle protein degradation. In summary, in rodent models and patients that respond to catabolic conditions, the activation of caspase-3 increases and this response stimulates increases in muscle protein degradation: firstly, caspase-3 performs an initial cleavage of complexes of muscle proteins, providing substrates for degradation by the UPS; and secondly, it stimulates the proteolytic activity of the proteasome. These properties exert a "feed-forward" stimulation of muscle proteins when caspase-3 is activated.

The calpains have also been suggested as a protease that initially cleaves myofibrillar proteins to provide substrates for degradation by the UPS. Calpains are calcium-dependent, cysteine proteases that are activated in muscular dystrophy or sepsis-induced

muscle wasting [132,133]. Their role in the digestion of muscle proteins in other conditions is unclear and the muscle wasting induced by CKD or conditions characterized by impaired insulin/IGF-1 signaling is not blocked by the inhibition of calpain activities.

Another contributor to CKD-induced muscle wasting is abnormal satellite cells. These cells are located underneath the basal lamina of myofibrils and function as muscle “stem” cells. Specifically, when muscles are injured or when muscle mass is low, satellite cells proliferate and then differentiate into myofibrils to increase the number and size of myofibrils [134]. Moreover, IGF-1 is a regulator of satellite cell responses and since we find that CKD impairs the proliferation and differentiation of satellite cells, these responses are notable because CKD impairs IGF-1 intracellular signaling [135].

### Cytokine-induced muscle wasting

In addition to experimental information that increases in inflammatory cytokines stimulate muscle protein losses, there is evidence that dysfunctional mitochondria plus oxidative stress stimulate losses of muscle proteins [136–138]. Interestingly, certain inflammatory cytokines, particularly those stimulated by CKD and diabetes, exhibit reduced insulin sensitivity that appears to be a product of elevated circulating levels of tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) as a stimulus leading to insulin resistance and loss of muscle mass. Insulin-responsive cells including adipocytes and hepatocytes produce TNF- $\alpha$ , interleukin 6 (IL-6), and interleukin 1 (IL-1), and both tissue and circulating cytokine levels are increased by a high-fat diet [139]. In mice with insulin resistance, a high-fat diet actually increases the insulin resistance [140]. Hung et al. demonstrated that an IL-1 receptor antagonist can markedly suppress circulating levels of inflammatory cytokines in hemodialysis patients [141]. What is not known is whether these complications act synergistically to activate protein wasting in rodent models or patients with evidence of inflammation.

### Myostatin

Myostatin is a member of the transforming growth factor- $\beta$  (TGF- $\beta$  family of secreted proteins), but unlike TGF- $\beta$ , myostatin is predominantly expressed in skeletal muscle (low levels are also present in cardiac muscle and adipose tissues). In skeletal muscle, the myostatin precursor, premyostatin, is cleaved to promyostatin, which functions to produce an inactive, “latent complex.” Myostatin is released from this complex and binds to a high-affinity, type-2 activin receptor (ActRIIB)

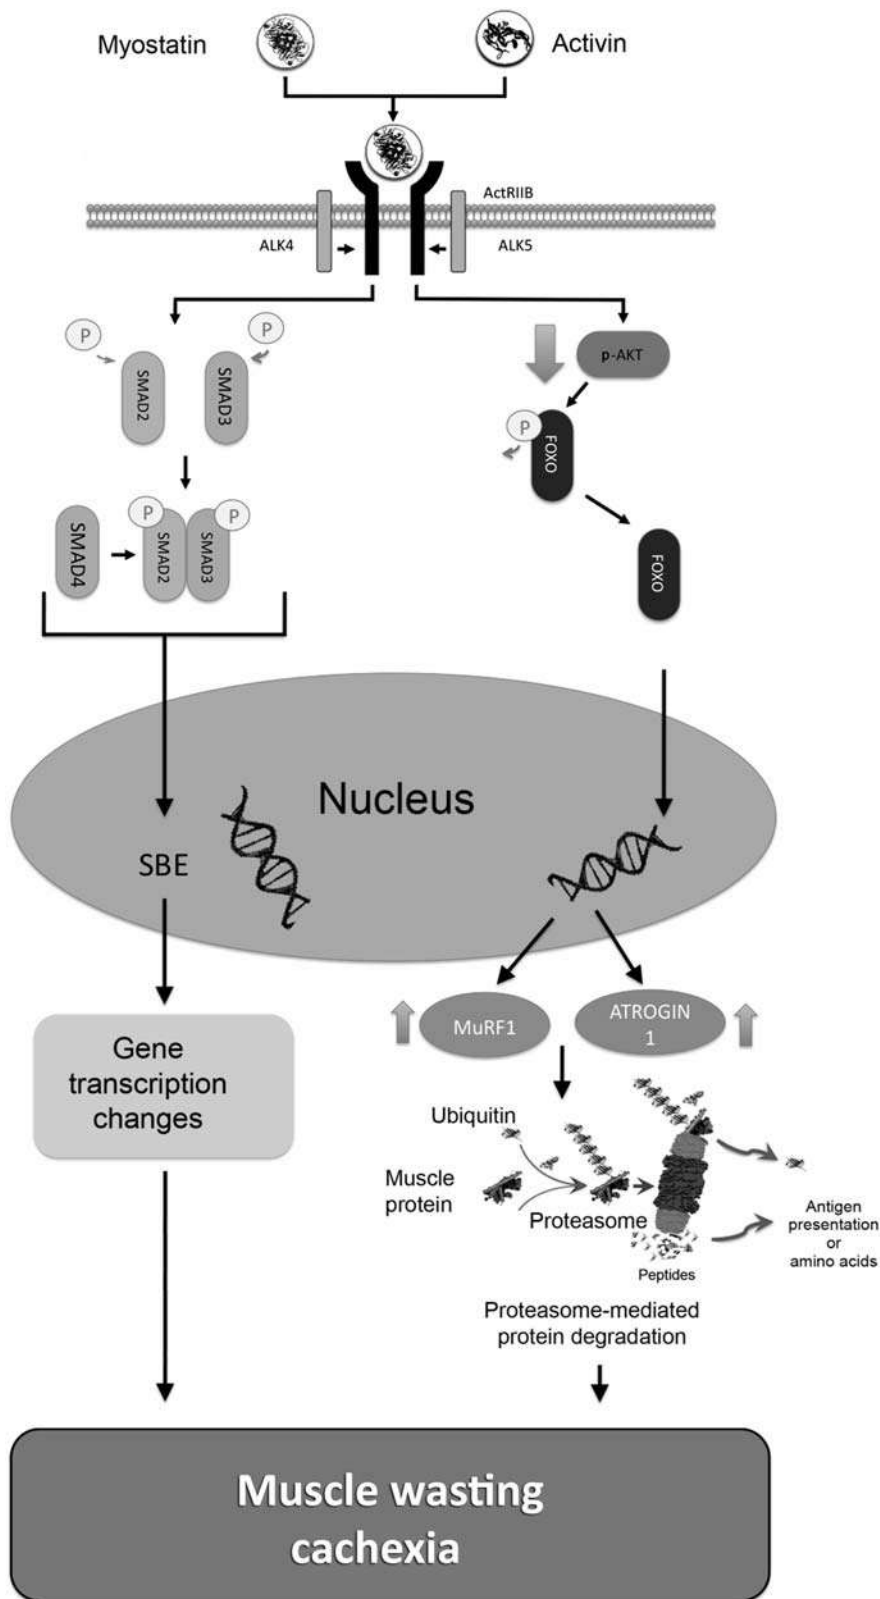

present on muscle membranes [58]. Activation of this receptor leads to phosphorylation of SMAD transcription factors that regulate gene transcription. Notably, other TGF- $\beta$  family members (e.g., activin A) can bind to ActRIIB and stimulate the same intracellular signaling pathway (Fig. 2.2). In skeletal muscle, the myostatin protein and its signaling pathway are increased in muscle-wasting conditions such as aging, responses to prolonged bed rest, AIDS, kidney failure, or heart failure [11,142–144]. Likewise, in models of cancer cachexia, glucocorticoid administration, mechanical unloading, and space flight, there are high levels of myostatin in muscle [145,146]. This is relevant because there is abundant genetic evidence that myostatin plays a pivotal role in regulating skeletal muscle mass and function. For example, deletion of the myostatin gene in mice causes a dramatic increase in the sizes and number of skeletal muscle fibers. Besides mouse phenotypes, cattle, sheep, dogs, and a human bearing a loss-of-function myostatin mutation will exhibit an enormous increase in muscle mass [147–149]. These myostatin mutations can influence athletic performance: whippet dogs bearing a single copy of the myostatin mutation are among the fastest dogs in racing. However, whippets bearing two copies of the same mutation have such a large amount of muscle mass that they win no races. Likewise, myostatin polymorphism in elite thoroughbred horses suggests these horses have a decided advantage regarding swiftness [150]. Since myostatin deficiency does produce muscle hypertrophy and can improve physical performance, manipulating myostatin might block muscle wasting, and this could be the basis for a therapeutic strategy.

Myostatin inhibition in CKD mice was found to be associated with decreased circulating levels of inflammatory cytokines and especially, IL-6. In fact, earlier results demonstrated that an increase in IL-6 and the acute phase protein, serum amyloid A acted synergistically to impair intracellular IGF-1 signaling [151]. The resulting decrease in p-Akt in muscles led to acceleration of protein degradation in muscles. Muscle treatment with the antimyostatin peptibody corrected these responses and blocked the CKD-induced muscle catabolism. Finally, it was shown that treatment of cultured muscle cells with TNF- $\alpha$  actually raised myostatin production in muscle cells. However, treatment of muscle cells with myostatin increased the production of IL-6. To date, treatment of CKD patients with the antimyostatin peptibody has not successfully blocked the losses of muscle mass.

### Albumin and other markers of malnutrition

There is a familiar relationship between low values of serum albumin and increased mortality in CKD and

**FIGURE 2.2** Myostatin and Activin bind to ActRIIB receptor and stimulate muscle degradation by activation of SMAD transcription factors that promote muscle degradation. The ActRIIB receptor also stimulates the Ub-proteasome pathway. *SBE*: SMAD binding element.

dialysis patients. Initially, this relationship was generally attributed to eating an inadequate diet (i.e., malnutrition-induced loss of muscle mass) [152]. This perception is erroneous for the following reasons. First, if protein malnutrition was the cause of defects in protein stores, then low values of serum albumin should be corrected by merely altering the diet. Unfortunately, changing the diet rarely reverses the loss of protein stores in patients with CKD. Serum albumin should be used primarily as a predictor of hospitalization and mortality rather than a sensitive index of nutritional status or adequacy of dietary protein.

It is useful to track changes in body mass index (BMI) and serum potassium and phosphorus levels in patients with advanced CKD and ESRD patients because low values can indicate an increased risk of malnutrition. Alternatively, decreasing values of BMI may be influenced by changes in total body water related to increased salt intake. In CKD patients with limited residual renal function, the expected interdialytic weight gain, as a percentage of body weight, is between 2% and 5%; <2% fluid gain can indicate inadequate fluid or food intake and may predict a decrease in body mass [153]. It is critically important to screen patients for the possibility of underdialysis (using urea kinetic modeling: Kt/V) resulting in accentuated uremic symptoms such as nausea, taste changes, acute or chronic gastrointestinal dysfunction, fatigue, and depression. Kinetic modeling can be used to estimate protein consumption, by measuring the normalized protein nitrogen appearance (nPNA), and nitrogen balance is best achieved by consuming 1.2 g/kg of protein daily in this group of patients (see [Chapter 31: Nutritional Management of Maintenance Hemodialysis Patients](#), and [Chapter 32: Nutritional Management of Chronic Peritoneal Dialysis Patients](#)) [154,155]. It is also vital to assess the socioeconomic status and address food insecurity with assistance programs, if needed.

## Defining decreased protein stores

Reduced protein stores in patients with CKD will contribute to increases in their morbidity and mortality but it is difficult to assign a cause–effect relationship with malnutrition. A significant dilemma in establishing a cause–effect relationship is the lack of consensus surrounding definitions of muscle wasting. In 2008 the International Society of Renal Nutrition and Metabolism proposed that low values of serum albumin, prealbumin, and cholesterol plus abnormalities in body weight and anthropometry could identify patients with CKD who

have lost protein stores [156]. They also suggested a new descriptive term, protein-energy wasting or PEW, as a method of classifying affecting patients. Other diagnoses used to detect reduced protein stores in CKD patients were abandoned because they were imprecise. For example, sarcopenia was discarded because it generally describes the loss of muscle mass associated with aging. Cachexia was discarded because it implies a more severe state of protein depletion. An alternative Consensus Conference concluded that the loss of muscle mass without loss of adiposity be labeled as cachexia [157]. Others have recommended that a cachexia diagnosis should include a 5% loss of edema-free body weight within 12 months plus anthropometric evidence of muscle wasting, and the evidence of inflammation and hypoalbuminemia. We have not identified a more accurate diagnosis of lost muscle mass. But, there is interest in using the new tools based on loss of muscle mass identified by CT scanning or magnetic resonance imaging (MRI) but the cost for follow-up evaluations could be prohibitive [158].

Although less expensive, estimates of lean body mass from bioelectric impedance and dual-energy X-ray absorptiometry are of limited value because they do not readily distinguish between fluid and tissues, and the lean body compartment is derived [159]. Finally, these problems can be avoided by measuring body composition by the presence of potassium and nitrogen isotopes using whole-body counters [160]. This measurement is noninvasive and accurate, but the technique is only available at a handful of sites in the world. Recently, a noninvasive method to estimate muscle mass based on creatine (D3-creatine) dilution using fasting morning urine has been developed. In one report, D3-creatinine urinary enrichment from the day provided muscle mass estimates that were correlated with MRI ( $r=0.88$ ,  $P<.0001$ ) [161]. The technique relies on a consistent fraction of the ingested label to be incorporated in the total creatinine pool and has intrasubject variability as a result of urine collection methods. Furthermore, the reliability of these measurements is unknown in patients with labile SCr and advanced CKD, but the test may be useful in appropriate clinical and research settings.

## Protein supplementation in dialysis

Protein-energy wasting estimated from circulating albumin affects up to 60% of hemodialysis patients and is a strong predictor of mortality. Hemodialysis is associated with the loss of 10–12 g of amino acids, and in peritoneal dialysis patients, 5–15 g of albumin is lost daily depending on the number of exchanges [162,163]. The catabolism related to the dialysis is not limited to the time patients are exposed to the

procedure; Ikizler et al. measured protein synthesis and degradation in fasting hemodialysis patients using standard techniques of labeled amino acid turnover and found the catabolic state endured after dialysis treatment [164]. Specifically, they measured the components of protein metabolism before, during, and at 2 hours after completing the dialysis treatment. At all three points, protein degradation exceeded protein synthesis suggesting that the dialysis procedure can activate metabolic pathways that stimulate the loss of body protein stores.

Clinical practice guidelines for dialysis patients recommend nutritional counseling and adding oral nutrition supplements as first-line treatment. If this proves ineffective, then enteral tube feeding is recommended. When oral or enteral feedings are not feasible, then parenteral nutrition is an option. The effect of protein supplementation using intradialytic parenteral nutrition during dialysis (IDPN) has been investigated, and protein balance is improved [165]. Specifically, when IDPN is given during dialysis, it improved both the rates of protein synthesis and degradation, but it did not prevent the persistent increase in protein degradation after dialysis. In another evaluation, the investigators compared the responses associated with the administration of IDPN to those induced by an oral nutritional supplement given during hemodialysis. Protein balance improved with both IDPN and the oral supplement, but whole-body protein balance was still negative [166]. These careful studies indicate that dialysis must activate or stimulate catabolic pathways in CKD patients, increasing the risk of muscle protein wasting. The results indicate that the unidentified, catabolic pathways are not “turned off” by increasing dietary constituents. An early report by Capeli et al. examining clinical outcomes in patients treated with IDPN showed correction of hypoalbuminemia and improved mortality, and a more recent study showed significant improvement in prealbumin levels [167,168]. However, other investigators have not found that IDPN decreases hospitalizations or improves mortality [169,170]. After two years, the supplement had improved the serum concentration of albumin. Unfortunately, the supplement did not improve mortality, BMI, laboratory markers of nutritional status, or the rate of hospitalization. Taken together, these reports suggest that correcting metabolic abnormalities induced by ESRD or at least blunting their physiologic influence should be further investigated.

### **Protein metabolism post-kidney transplantation**

There have not been many investigations of mechanisms affecting protein metabolism in patients following

kidney transplantation. Available results indicate that post-kidney transplant, patients gain significant increases in weight just after successful kidney transplantation and in subsequent years. Could the post-kidney transplant gain in weight arise from improvements in protein status, to the accumulation of salt and water or to accumulation of fat mass, or to a combination of these factors? It has been speculated that the post-transplant weight gain could be due to the accumulation of muscle mass but increased size of this organ was not uncovered in a recent report [171,172]. In other analyses, it has been concluded that muscle mass did not increase in kidney transplant recipients [173].

It is well established that insulin resistance is a serious complication of patients with either CKD or kidney transplantation, extending even to the development of post-transplant diabetes [174]. The increase in the body weight of kidney transplant patients is primarily related to increased fat mass. Whether this altered body composition is due to glucocorticoid-induced altered fuel metabolism is unclear. However, the development of insulin resistance would suppress muscle mass and account for the observation that muscle mass did not increase despite a gain in both body weight and physical activity [175]. On the other hand, analyses of body composition indicate that there is a demonstrable association between the accumulation of visceral adipose tissue and the development of insulin resistance.

Factors that may contribute to the development of weight gain and insulin resistance include corticosteroid treatment, but this is not the only cause since insulin resistance can develop in kidney transplant patients that are treated with steroid-sparing protocols. For example, corticosteroid withdrawal from kidney transplant patients after only 7 days revealed that both placebo-treated and corticosteroid-treated patients gained a significant amount of weight [176,177]. Thus in patients receiving only low amounts of corticosteroids, this hormone is unlikely to be a primary factor accounting for weight gain. Other factors associated with the increase in weight include African American race, young age, female gender, modality of dialysis, use of tacrolimus-based immunosuppression, and poorly defined genetic factors [178–180].

## **Conclusion**

There is over a century-old observation that loss of kidney function leads to altered protein metabolism, which affects the course of kidney disease by producing uremic toxins, stimulating inflammation, and a deterioration of homeostatic functions of the kidney. Despite efforts directed at identifying physiologic and molecular mechanisms that change protein metabolism, there remain

unanswered questions: (1) how are specific uremic toxins generated, and how can the toxicity of potential toxins be tested and prevented? (2) What are the mechanisms that result in loss of muscle mass and, ultimately, increasing frailty, morbidity, and mortality? (3) In CKD, what is the mechanism that raises circulating inflammatory cytokines, increases glucocorticoid production, and impairs insulin/IGF-1 signaling leading to proteolysis of body protein stores? Not surprisingly, multiple techniques have been investigated to determine if they can successfully block muscle protein losses and the loss of kidney function. A potentially successful strategy has been to limit the amount of protein and acid-generating compounds in the diets of patients with CKD. This can be accomplished either by providing alkali therapy or by modifying diet to include increased amounts of fruit and vegetables in meals and by prescribing low-protein diets or very low-protein diets that provide 0.3 g protein/kg/day plus ketoacids to patients with CKD. Notably, the success of changing the diet requires regular evaluations of compliance with dietary interventions; this is possible when compliance is based on analyses of urea kinetics. In designing diets of patients with CKD, there are other factors to consider besides protein and calorie adequacies, namely, diets rich in protein also are rich in phosphates and salt. This is relevant because inattention to their role in the design of diets can interfere with the function of drugs such as inhibitors of the renin–angiotensin–aldosterone that can slow the progression of CKD. As long as there is kidney disease, there will be a need for a trained focus on nutrition, and as new therapeutics enter the market for CKD, it would be wise to assess their influence on protein metabolism.

# Carbohydrate metabolism in chronic renal disease

*Marcin Adamczak<sup>1</sup>, Eberhard Ritz<sup>2</sup> and Andrzej Wiecek<sup>1</sup>*

<sup>1</sup>Department of Nephrology, Transplantation and Internal Medicine, Medical University of Silesia, Katowice, Poland

<sup>2</sup>Ruprecht Karl University of Heidelberg, Heidelberg, Germany

## Introduction

In patients with chronic kidney disease (CKD), disorders of carbohydrate metabolism are encountered at different levels of the insulin-glucose cascade. The two major abnormalities that underlie glucose intolerance in CKD are resistance to the peripheral action of insulin and impaired insulin secretion. When these two metabolic disturbances are present glucose intolerance ensues [1]. Patients with CKD stage 5 are frequently resistant to the peripheral action of insulin. Consequently, plasma insulin concentrations tend to be higher at any given rate of insulin secretion [2,3] (Table 3.1).

## Insulin resistance

Insulin resistance is a state of impaired biological response to normal circulating levels of insulin that is accompanied by hyperinsulinemia to maintain normal plasma glucose concentration. Patients with insulin resistance experience lipid accumulation and increase in lipolytic activity in adipose tissue.

As first reported in detail by Westervelt and Schreiner, using the forearm perfusion technique, peripheral glucose uptake is reduced in CKD [5]. This observation was confirmed by DeFronzo and Alvertrand [6] using the gold standard method, the euglycemic insulin clamp technique, which allows to quantitate the amount of glucose metabolized per unit of insulin. Such peripheral resistance to insulin is seen even in the early stages of CKD. In a study of glucose and insulin in renal disease (SUGAR) [7], it was shown that in nondiabetic patients with moderate to severe CKD, glucose intolerance and hyperinsulinemia are common. In this study,

insulin sensitivity measured by the euglycemic insulin clamp technique was unrelated to the eGFR. Overall, demographic factors, physical activity, diet, smoking, adiposity, and lean body mass explained decrease of insulin sensitivity in CKD [7]. What is the prevalence of insulin resistance in CKD patients? In the ULSAM study based on the euglycemic insulin clamp technique, the prevalence of insulin resistance in Caucasian elderly men with an eGFR <60 mL/min, was 24% [8]. In the study performed in hemodialysis (HD) patients, the prevalence of insulin resistance measured by the homeostatic model (HOMA-IR) was 32% [9].

Both liver and kidney are the major sites of glucose production in the fasting state [10,11]. Liver and skeletal muscles are the major sites of peripheral glucose uptake. The available data indicate that glucose production by the liver is not altered in CKD. Specifically, DeFronzo and coworkers documented that baseline hepatic glucose production and its suppression by insulin were not altered in patients with CKD [3,6]. In addition, glucose uptake by the liver seems to be not affected in CKD [6]. The renal contribution to glucose production has long been grossly underestimated and is in fact quite substantial [12].

The main site of decreased insulin sensitivity is skeletal muscle. The defect is not at the level of the insulin receptor: in skeletal muscles of rats with chronic uremia the numbers and affinities of the receptors are normal [13], as well as, insulin receptor kinase activity [14]. The defect is presumably at the postreceptor level [15].

There is also information on insulin postreceptor defect in CKD and uremia. When the  $\beta$  chain of the receptor has been phosphorylated, a complex series of interactions follows involving insulin receptor substrate

TABLE 3.1 Abnormalities of carbohydrate metabolism in chronic kidney disease.

- Usually normal fasting blood glucose, but tendency to spontaneous hypoglycemia
- Fasting hyperinsulinemia with prolonged insulin half-life
- Elevated plasma glucagon and growth hormone concentrations
- Impaired glucose tolerance

(IRS) as well as numerous cofactors [16,17]. More distal effects (e.g., stimulation of proliferation) are mediated via the mitogen-activated protein kinase pathway and the inositol-triphosphate (IP3) pathways.

The latter is responsible for the upregulation of the insulin-regulated glucose transporter (GLUT-4). The PI3-K complex is a heterodimer composed of an 85-kDa (p85) regulatory subunit and a 110-kDa (p110) catalytic subunit. The subunits and the p85–p110 complexes are differentially regulated by glucocorticoids [18,19]. Stimulation of p85 expression by glucocorticoid treatment leads to the reduction of PI3-K activity [19]. This may be relevant because glucocorticoid synthesis is increased in uremia [20].

In uremia the insulin-dependent glucose uptake is altered. GLUT-4 is unique to muscle and adipose tissue. The expression of GLUT-4 in muscle cells of subtotaly nephrectomized rats is reduced [21]. Carbamylation of proteins is a common finding and modifies signal transduction and translocation of GLUT-4. It has been shown that *N*-carbamoyl-L-asparagine reduces insulin-sensitive glucose uptake by interfering with GLUT-4 activity [22].

As mentioned earlier, insulin-resistant frequently occurs even at the early stages of renal disease and becomes even highly prevalent in patients with advanced CKD, however. The resistance to the peripheral action of insulin markedly improves after several weeks of HD and of peritoneal dialysis (PD) [23,24]. Presumably, an unidentified dialyzable uremic “toxin,” possibly a protein breakdown product, is involved in the genesis of impaired insulin action. Sera of uremic patients contain a compound that inhibits glucose metabolism by normal rat adipocytes [25]. This compound with a molecular weight of 1–2 kDa is specific for uremia, because it is not found in nonuremic patients with insulin resistance. Hippurate accumulates in the blood of patients with CKD and inhibits glucose utilization by rat diaphragm, brain, kidney cortex, and erythrocytes. It may therefore contribute to insulin resistance of patients with CKD [26]. It was also found that p-cresyl sulfate promotes insulin resistance associated with CKD [27].

A number of further factors have been identified which are involved in the genesis of insulin resistance in kidney disease and some of them are potential targets for intervention.

Increased visceral fat is an important risk factor for insulin resistance both in the general population and in CKD [28]. Insulin resistance by HOMA-IR is closely linked to both fat mass and body mass index (BMI) in CKD [28]. Ramos et al. [29] documented that even in nonobese, nondiabetic patients with advanced CKD, BMI and adiposity were associated with increased F2-isoprostanes and C-reactive protein plasma concentrations and negatively correlated with protein thiol's plasma concentrations. They concluded that adiposity amplifies oxidative stress and inflammation [29].

It has been postulated that resistin, a hormone derived from adipose tissue, is involved in the genesis of insulin resistance [30]. Plasma resistin concentrations are high in CKD patients, probably the result of diminished renal clearance [31]. In CKD, however, no relation was found between insulin sensitivity and plasma resistin concentrations [31].

A sedentary lifestyle causes insulin resistance [32]; conversely, exercise training improves insulin sensitivity. It was shown both in experimental [33] and clinical studies [34,35] that this applies for CKD as well.

Plasma concentrations of the insulin antagonists glucagon [36,37] and growth hormone [38,39] are frequently elevated in CKD. It has been proposed that these two hormones contribute to insulin resistance. However dialysis improves insulin sensitivity without changing the concentrations of growth hormone and glucagon [40,41].

Metabolic acidosis is frequent in CKD [42]. Observational studies in CKD patients with the euglycemic insulin-glucose clamp technique showed that metabolic acidosis is associated with insulin resistance [22,43,44]. Results of experimental studies suggest that metabolic acidosis leads to insulin-induced internalization defects and accelerates the dissociation of insulin from its receptor [45,46]. A causal role in insulin resistance is suggested by the observation that correction of acidosis by bicarbonate improves insulin resistance in CKD patients [44,47].

A finding with a major clinical relevance is the observation that in uremia major insulin resistance is caused by inflammation. The molecular pathways following insulin binding to its receptor includes tyrosine phosphorylation of members of IRS family. This process triggers translocation of GLUT-4 from intracellular stores to the cell membrane [48]. Conversely, serine phosphorylation of IRS-1 abrogates the association between IRS-1 and insulin receptor leading to a state of insulin resistance [49]. Inflammatory mediators such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) may activate serine kinases such as c-jun-NH2 terminal-kinase (JNK) and I $\kappa$ B kinase (IKK) which phosphorylate serine residues of IRS-1 and disrupt insulin signaling [50].

Insulin resistance is involved in the development of a catabolic state during uremia. Muscle catabolism in inflammatory states is mediated by proinflammatory cytokines, for example, interleukins 1 and 6 (IL-1 and IL-6) and TNF- $\alpha$  [51–53]. These cytokines act also on the satiety center [54,55]; this may explain the tight relationship between anorexia and the plasma concentration of the proinflammatory cytokines in HD patients [56,57].

Another observation is the potential role of anemia which by decreasing tissue oxygenation may lead to insulin resistance [58] which is ameliorated by erythropoietin treatment [59–61].

Low plasma concentration of 1,25-dihydroxycholecalciferol (1,25(OH) $_2$ D $_3$ ) is common in CKD patients, especially at CKD stage 4 or 5 [62]. It was shown that, in CKD 3 and 4 patients, therapy with an active form of vitamin D or with cholecalciferol did not affect insulin resistance [63]. These results suggest that vitamin D has no role in the pathogenesis of insulin resistance in CKD. In contrast, metaanalysis of 17 clinical trials completed in HD patients showed that vitamin D therapy (mainly as an active form) improves insulin sensitivity [64]. The mechanisms by which vitamin D improves insulin sensitivity in HD patients remain unknown.

Finally, it is known that angiotensin II (Ang II) [65,66] interferes with insulin sensitivity in individuals without kidney disease. Ang II contributes to insulin resistance in CKD as suggested by the observations of Satrapoj et al. in HD patients. Indeed, valsartan reduced fasting insulinemia and insulin resistance as assessed by the homeostatic model (HOMA-IR index) [67]. Moreover, Cioni et al. showed in PD patients that telmisartan improves insulin sensitivity also measured by HOMA-IR indexes [68].

## Consequences of insulin resistance

Insulin resistance seems to be a clinically important parameter, because in insulin resistant patients CKD progression, may be accelerated [69,70]. In CKD patients, insulin resistance is closely associated with increased cardiovascular risk [8,71]. Shinohara et al. [71] followed 183 nondiabetic HD patients for more than 5 years. CV deaths by Kaplan–Meier estimation were significantly more frequent in subjects in the top tertile of insulin resistance, assessed by the HOMA-IR index, compared to the lower tertiles. The adverse effect of insulin resistance on mortality was independent of body mass, hypertension, and dyslipidemia. In CKD patients, insulin resistance is closely associated with cardiovascular risk factors, including oxidative stress [72], chronic inflammation [72], and endothelial dysfunction [73]. Moreover, insulin resistance may

contribute to hypertension [74]. It was shown that insulin resistance increases salt sensitivity via an increased tubular sodium reabsorption [75]. Insulin resistance might also lead to lipid abnormalities. Insulin is an important regulator of lipoprotein lipase activity (LPA). Insulin resistance is associated with reduced LPA activity [76]. Lipoprotein lipase plays a major role in triglyceride removal. In CKD patients, LPA activity is reduced and presents the major cause of hypertriglyceridemia [77]. Further support for the role of insulin in the genesis of dyslipidemia is provided by the observation that administration of insulin to uremic rats corrects the defect in LPA as well as hypertriglyceridemia [78]. Insulin resistance may also participate in the pathogenesis of malnutrition commonly found in CKD patients [48,79]. In rats with acute kidney injury, protein degradation is increased in perfused or incubated muscle. This defect is closely related to abnormalities in insulin-dependent carbohydrate metabolism [80]. Insulin deficiency (or resistance) stimulates breakdown of muscle proteins and activates a common proteolytic pathway via the ubiquitin-proteasome system [81,82]. Therefore insulin resistance may also contribute to increased protein catabolism and malnutrition in CKD patients.

## Insulin secretion

Insulin secretion by the  $\beta$  cells of the pancreatic islets is a complex process. The  $\beta$  cells are stimulated both by nutrients (glucose, amino acids, and fatty acids) and nonnutrient agents, for example, hormones and neurotransmitters. The islets use different mechanisms to detect nutrient and nonnutrient stimuli, but insulin secretion uses the same intracellular processes irrespective of whether the  $\beta$  cells are activated by nutrient or nonnutrient secretagogues [27].

Glucose-induced insulin secretion involves glucose uptake by the  $\beta$  cells, followed by glucose metabolism and production of adenosine triphosphate (ATP). ATP facilitates the closure of ATP-dependent K channels, followed by cell membrane depolarization and subsequent activation of voltage-sensitive Ca channels. As a consequence, calcium enters the islets causing an acute rise in cytosolic Ca concentration, thus triggering the secretion of insulin (through exocytosis of insulin-containing granules) [83].

A number of studies showed that insulin secretion is impaired in CKD [84–87]. One factor responsible for impaired insulin secretion in CKD is high plasma parathormone (PTH) concentration. Insulin secretion, as assessed by the hyperglycemic clamp technique, is improved when the parathyroid gland is suppressed [88,89]. Using the technique of isolated pancreatic islets

the underlying molecular mechanisms have been elegantly demonstrated in subtotaly nephrectomized (SNX) rats by Fadda et al. [84]; insulin release triggered by glucose (but not by the alternative agent glyceraldehyde) was diminished in SNX rats and this outcome was almost completely prevented by parathyroidectomy [84,90]. The mechanism underlying PTH-induced impairment of insulin secretion is an increase in cytoplasmic Ca concentration in pancreatic beta cells as a result of increased Ca entry, followed by decreased Ca extrusion and the resulting reduction of ATP content. As a result, closure of ATP-dependent K channels occurs with consecutive reduction of the glucose-induced Ca signal. Glucose-induced insulin secretion is impaired even in rats with normal renal function when they receive daily injections of PTH [90,91].

Apart from glucose, amino acids are stimuli triggering insulin secretion, the most potent being L-leucine [92], and an additional stimulus is K [93]. In CKD, such insulin secretion triggered by the alternative stimuli L-leucine [87] or K [85] is also impaired.

Similarly to animal experiments, in uremic patients, reduced insulin secretion in response to secretagogues is mainly the result of chronic PTH excess. This was documented by Mak and coworkers in children treated by hemodialysis, whose insulin secretion increased after parathyroidectomy [88,89].

$1,25(\text{OH})_2\text{D}_3$  affects insulin secretion as well. Islet cells express both vitamin D receptors [94,95] and vitamin D-dependent calcium-binding protein [96]. After administration of labeled  $1,25(\text{OH})_2\text{D}_3$ , radioactivity is retrieved in the cells [97]. Insulin secretion is impaired in vitamin D-deficient rats with normal renal function [98]; the defect is reversed by vitamin D [99]. This may be relevant for CKD, because acute intravenous administration of  $1,25(\text{OH})_2\text{D}_3$  to dialysis patients improved the early and late phases of insulin secretion [100].

### Insulin clearance

The kidney plays an important role in insulin metabolism and clearance. Insulin is filtered by the glomeruli and reabsorbed in the proximal tubule [101]. In normal subjects the renal clearance of insulin is about 200 mL/min [102]. This value exceeds the glomerular filtration rate (GFR), indicating that in addition, peritubular uptake of insulin takes place [103]. It is estimated that 6–8 U of endogenous insulin are removed daily by the kidney, accounting for 25%–40% of the total removal of endogenous insulin. A decrease in the metabolic clearance rate of insulin is demonstrable in patients with GFR <40 mL/min; a significant prolongation of the insulin half-life is observed when GFR falls below 20 mL/min [104]. The endogenous

insulin clearance increases remarkably when dialysis treatment is started; presumably, this is explained by an increase in insulin removal by liver and muscle.

In CKD patients, diminished renal [104] and extra-renal (liver and muscles) [105] insulin clearance accounts for fasting hyperinsulinemia. It also accounts for decreased insulin requirements in diabetic patients with impaired kidney function.

### Hypoglycemia

Hypoglycemia may lead to serious complications. Severe hypoglycemia may result in acute mental status changes such as: seizures and coma [106]. Clinical studies suggest that patients with hypoglycemia are more prone to cardiac arrhythmias [107] or to stroke [108].

Clinical observation showed that CKD patients, both diabetic and nondiabetic, are particularly at hypoglycemia risk [109–112]. In a retrospective cohort analysis comprising 243,222 Veterans Health Administration patients, hypoglycemic episodes (<70 mg/dL) were more frequent in diabetic as well as nondiabetic patients with CKD compared to no CKD; the risk of death within 1 day after hypoglycemia <70 mg/dL was markedly elevated [112].

The mechanism underlying spontaneous hypoglycemia in CKD patients is not completely elucidated. It is important to be aware of the fact that in contrast to the previous opinions gluconeogenesis is not restricted to the liver. Recent studies document that the kidney contributes to no less than 40% of overall gluconeogenesis [12]. In type 2 diabetic patients, the overall glucose production is increased by as much as 300%; hepatic and renal gluconeogenesis contribute equally to this increase [113]. Moreover, a reduction in hepatic glucose production was found, due to diminished availability of substrate for gluconeogenesis [109]. Malnutrition, impaired glycogenolysis, and impaired degradation of insulin may all contribute to spontaneous hypoglycemia [106,114]. Nondiabetic HD patients treated with glucose-free dialysate frequently develop hypoglycemia [114]. However nowadays most dialysate solutions contain 200 mg/dL glucose to avoid these events. In diabetic patients with CKD, decreased degradation of the administered insulin may result in higher than expected blood insulin levels. This may potentially precipitate hypoglycemia. Repeated episodes of hypoglycemia are occasionally the first clinical sign drawing attention to the presence of impaired renal function. Careful adjustment of the insulin dose is then needed. Some researchers reported that insulin dose could be reduced by 40%–50% [106]. When diabetic patients with impaired renal function are treated with antidiabetic agents, it is important to consider that some of these agents or their active metabolites

are cleared via the kidney and cumulate in CKD patients [106]. Therefore some of these drugs become contraindicated, and appropriate dose adjustment is necessary for the others (see below).

## Carbohydrate metabolism in patients with renal replacement therapy

### Patients undergoing maintenance hemodialysis

The initiation of renal replacement therapy by HD reduces insulin resistance. This was first reported by Kobayashi et al. [22] in a study using the hyperinsulinemic–euglycemic clamp technique. It has also been shown that the use of high-flux membranes lowers insulin resistance in HD patients compared to treatment with low-flux membranes [115,116]. It is relevant that many uremic patients with diabetes have so-called burnt-out diabetes [117], i.e., their, hyperglycemia disappeared after weight loss resulting from anorexia. On the other hand, in patients with terminal uremia and no known history of type 2 diabetes, but with a pathological oral glucose tolerance test, diabetes may reappear after refeeding following the start of HD treatment. This was seen in 10% of type 2 diabetic patients entering the HD program.

In nondiabetic and particularly diabetic HD patients the blood concentrations of glucose and insulin may be affected by the dialysis procedure and particularly by the dialysate glucose concentration. Blood glucose is lost into the dialysate downhill, a concentration gradient, if the dialysate is glucose free; therefore glucose-free dialysate is currently no longer used. Today, the usual dialysate glucose concentrations range between 100 and 200 mg/dL; the net effect will be lowering of markedly elevated glucose levels and protection against hypoglycemia during dialysis sessions [118]. Plasma insulin levels may also decrease during HD sessions as a result of potential glucose load (depending on dialysate glucose concentration) and of insulin clearance (the rate of loss varying between membranes).

Additional metabolic effects of dialysis include improved insulin sensitivity and potential decrease of counter-regulatory hormones (e.g., growth hormone), etc. In dialyzed diabetic patients, signs and symptoms of hyperglycemia may be modified: in addition to the classical signs, that is, thirst, fluid overload, and severe hyperkalemia, the absence of polyuria precludes volume contraction and may even cause volume expansion or pulmonary edema, particularly in the presence of excessive thirst. Further potential complications of hyperglycemia include increased blood pressure, altered mental status, nausea, and gastroparesis, but symptoms and signs are frequently nonspecific or lacking.

Antidiabetic therapies require special consideration in diabetic HD patients (see also below). The insulin dose must be reduced, often by as much as half. Rapid-acting insulin analogs are less likely to cause hypoglycemia than regular or long-acting insulin, because their pharmacokinetics are less affected by renal failure [119]. Most oral antidiabetic drugs are contraindicated in CKD stage 5 patients, and on dialysis, thiazolidinediones (TZDs), meglitinides, and dipeptidyl-peptidase 4 (DPP-4) inhibitors are the drugs that can be used in HD patients [106,120].

### Peritoneal dialysis patients

The initiation of renal replacement therapy by PD reduces insulin resistance as shown by Kobayashi et al. [22]. By contrast, some patients develop new-onset hyperglycemia after the start of PD, presumably as a result of high peritoneal glucose load [121,122]. PD patients tend to have higher fasting glucose, blood HbA1c, and HOMA-IR indices compared to hemodialyzed patients, possibly as the result of high glucose load and weight gain [123,124]. Depending on the dwell time and the exposure to high glucose PD solution, up to 80% or more of glucose in the PD solution is absorbed, accounting for a daily glucose load of up to 100–300 g of glucose [125,126]. The absorption of glucose from the dialysis solution predisposes to hyperinsulinemia, weight gain, and insulin resistance. Icodextrin, an osmotically active glucose polymer, can be used as an osmotic agent to substitute for glucose. Clinical studies indicate that reduction of hyperinsulinemia and increased insulin sensitivity can be achieved by long-term use of icodextrin-containing PD solutions for overnight exchanges [127,128].

### Kidney transplant recipients and new-onset diabetes after transplantation

The first description of diabetes mellitus as a complication of kidney transplantation dates back to 1964 [129]. Baseline risks that predispose kidney graft recipients to new-onset diabetes after transplantation (NODAT) include advanced age, obesity, male gender, hepatitis C virus infection, nonwhite ethnicity, and family history of diabetes, which are inherited, as well as, acquired defects in insulin sensitivity and  $\beta$  cell function [130,131]. The high incidence of NODAT in predisposed individuals during the first months after transplantation reflects superimposition of new transplant-specific factors upon a predisposing baseline metabolic milieu. The best documented transplantation-specific factors include immunosuppressive agents, for example, glucocorticoids, calcineurin inhibitors (cyclosporine and particularly

tacrolimus), sirolimus, and weight gain after transplantation [130,131] (Table 3.2).

NODAT will become even more frequent in the future given the current pandemic of obesity. Based on ADA (American Diabetes Association) criteria of diabetes mellitus, Cosio et al. [132] reported that 1 year after transplantation, the prevalence of NODAT was 13%. In one of the largest epidemiologic studies of NODAT, Kasiske et al. found, in 11,659 Medicare beneficiaries with a first kidney transplant, a cumulative incidence of NODAT of 9%, 16%, and 24% at 3, 12, and 36 months, respectively [133]. Many clinical studies in recipients of kidney and other solid organ transplants showed that NODAT is associated with an increased risk of graft failure as well as death when compared with graft recipients without NODAT [134]. The excess mortality is mainly attributable to a higher incidence of CV disease. The therapy of NODAT includes both nonpharmacological and pharmacological interventions: aggressive lifestyle modification, particularly dietary changes, exercise, and weight loss irrespective of whether the patient requires pharmacologic treatment for hyperglycemia or not [130,131,135]. The choice of antidiabetic agents depends mainly on transplanted kidney function. No antidiabetic drug is specifically contraindicated in patients after kidney transplantation, and pharmacological interventions are similar to those used in general diabetic population. The role of altering immunosuppression in an effort to improve glycemic control in patients with NODAT remains controversial [130,133]. Matas et al. compared the outcomes in NODAT kidney transplant recipients and concluded that prevention of acute rejection was more important than prevention of NODAT in preserving long-term kidney function [136]; therefore a

potential benefit of avoiding or reversing NODAT by a change of immunosuppressants (reducing or discontinuing corticosteroids or calcineurin inhibitors) must be weighed against the risk of precipitating acute or chronic rejection [130,135].

## Treatment of diabetes mellitus in diabetics with chronic kidney disease

### Target of treatments

At present, HbA1c blood concentration, which reflects average glucose plasma concentration over 8–12 weeks preceding the test, is widely used as a standard index for glycemic control in clinical practice in general population. However, the HbA1c blood concentrations may be interpreted erroneously in patients with CKD [137]. In CKD the lifespan of erythrocytes is shortened, and low HbA1c values may therefore be artificially low because of shorter exposure of erythrocytes to glycemia. Therefore HbA1c blood concentration underestimated poor glycemic control in CKD. Other possible markers of diabetes control monitoring (fructosamine and glycated albumin plasma concentrations) are also influenced by CKD-dependent factors. Both fructosamine and glycated albumin plasma concentrations depend not only on glucose concentrations but also on the proteinemia and protein turnover which might be influenced by nutritional status and degree of proteinuria [137].

The target HbA1c in CKD patients remains the subject of controversy. Experts from the European Renal Best Practice (ERBP) group suggest to achieve a target HbA1c value of 8.5 in patients with GFR of less than 45 mL/min/1.73 m<sup>2</sup> [138]. The KDIGO guidelines suggest that in CKD patients, the HbA1c blood concentration should be 7.0% or less to prevent microvascular complications [139]. Target over 7.0% should be recommended in CKD patients with comorbidities and risk of hypoglycemia (maintenance HD patients are in this group) [139]. The abovementioned expert opinion is based mainly on the results of metaanalysis of 10 studies (83,684 dialysis patients) [140]. In this metaanalysis, it was found that patients with a baseline HbA1c blood concentration of >8.5% are characterized by increased mortality (Hazard ratio-HR 1.14; 95% CI 1.09–1.19) when compared with patients with an HbA1c blood concentration of 6.5%–7.4%. An HbA1c blood concentration of <5.4% was also associated with an increased mortality risk (HR 1.29; 95% CI 1.23–1.35) [140]. Therefore there is no benefit of tighter glycemic control is assessed by an HbA1c of <6.5, whereas there was a clear risk for consequences of hypoglycemia episodes when glycemic control is tightened.

**TABLE 3.2** Risk factors that predispose kidney graft recipients to new-onset diabetes mellitus after transplantation.

#### Nonmodifiable risk factors

- Advanced age
- Male gender
- Nonwhite ethnicity
- Family history of diabetes
- Impaired glucose tolerance before transplantation

#### Modifiable risk factors

- Overweight and obesity
- Posttransplantation weight gain
- Hepatitis C virus infection
- Cytomegalovirus infection
- Immunosuppressive agents
  - Glucocorticoids
  - Calcineurin inhibitors (cyclosporine and to a greater extent tacrolimus)
  - Sirolimus and everolimus

## Drug management in diabetics with chronic kidney disease

### Metformin

Metformin is the only biguanide currently available. It increases insulin sensitivity by activating hepatic and muscle isoforms of adenosine monophosphate-activated protein kinase [141]. This causes decreased hepatic glucose production and increased glucose utilization. Metformin is the first-line antidiabetic therapy in general population because it has a proven impact on all causes and cardiovascular mortalities [142,143]. Moreover, with metformin, modest weight loss can be achieved. Additional advantages of metformin therapy include a low risk of hypoglycemia and a minor, but beneficial, effect on abnormal lipid profiles [141]. Retrospective, observational studies suggest that patients treated with metformin experience slower progression of CKD as compared to those treated with sulfonylurea agents. These data indirectly suggest nephroprotective properties of metformin. Metformin is cleared by renal excretion, and consequently, metformin accumulates in CKD [144]. The most dangerous side effect of metformin is lactic acidosis [141]. Large observational studies focused on the incidence of lactic acidosis in metformin-treated patients suggest that the risk of this complication is low and comparable to the risk observed in patients who are treated with the other glucose-lowering agents. In one of the analyses, lactic acidosis was found with a frequency of 3.3 per 100,000 metformin users and 4.8 per 100,000 patients not using this drug. In the same paper, hypoglycemia was found in 60 out of each 100,000 patients treated with metformin and 110 per 100,000 who were using other drugs; severe hypoglycemia was 20 times higher in those who were treated with other drugs as compared to metformin users [145]. In the context of advanced kidney disease the risk of lactic acidosis, is increased for two reasons: on the one hand, metformin accumulates, and on the other, the renal clearance of lactate is decreased [141]. The degree of kidney disease at which metformin is strictly contraindicated remains controversial [144]. According to some manufacturers and guidelines bodies, it has been stated that the drug can be used when GFR decreases to the range between 30 and 60 mL/min. If GFR is between 30 and 44 mL/min, the initial dose should not exceed 50% of the maximum dose (i.e., 1000 mg/day), whereas in the GFR range of 45–59 mL/min, it may be used in a full dose of 2000 mg/day. Metformin is contraindicated when GFR falls below 30 mL/min and should be strictly avoided in dialysis patients, however. It is strongly advised to carefully monitor the kidney function in diabetic patients treated with metformin.

### Sulfonylureas

Sulfonylureas enhance the pancreatic insulin secretion. As a result of increased plasma insulin concentration, weight gain and hypoglycemia are common side effects. The older sulfonylureas are predominantly metabolized in the liver to yield active metabolites which are cleared via the kidney along with unmetabolized drug [119,146]. In patients with kidney dysfunction, accumulation of the parent drug and of metabolites of some sulfonylurea compounds can lead to hypoglycemia. Consequently, these first-generation sulfonylureas should be avoided at least in patients with CKD. Among the second-generation sulfonylureas, glipizide and gliquidone are preferred in CKD patients. Glipizide and gliquidone are metabolized exclusively to the nonactive metabolites in the liver that are eliminated via the kidney [119,147]. Consequently, the risk of hypoglycemia in CKD patients is less. Nevertheless, because of the remaining risk of hypoglycemia, sulfonylureas should be used with caution even in mild to moderate CKD [119,146].

### Pioglitazone

The only currently available TZD is pioglitazone. It is a selective agonists of the peroxisomal proliferator-activated receptor- $\gamma$  (PPAR- $\gamma$ ) [119,146]. The ligands for these receptors are normally free fatty acids and eicosanoids. By activating PPAR- $\gamma$ , it decreases leptin levels and certain ILs, while serum adiponectin increases [148]. TZDs act as a prandial glucose regulators and improve insulin sensitivity. The PROactive trial demonstrated that treatment with pioglitazone reduced the risk of cardiovascular events and the benefit was independent from renal function [149]. TZDs are predominantly metabolized and eliminated by the liver [119,146]. Consequently, no dose adjustments is necessary in patients with advanced kidney disease. A major TZDs side effect is sodium retention, particularly in patients with CKD, causing weight gain with reduction of hematocrit, edema, and even pulmonary edema, particularly in patients with heart failure [146]. Further side effects include higher fracture rates of distal bones in women and gastrointestinal side effects [146].

### Meglitinides

The meglitinides, that is, repaglinide and nateglinide, are short-acting agents that bind to an ATP-dependent K channel on  $\beta$ -cell membranes (similar but not identical with that occupied by sulfonylurea); the resulting depolarization of pancreatic  $\beta$  cells causes Ca influx and increased insulin secretion [150,151]. Side effects of the meglitinides include hypoglycemia

and weight gain. One of the significant advantages of meglitinides is their safe administration in CKD patients, because these drugs are mainly excreted by hepatic clearance [146]. Repaglinide seems to be safer than nateglinide. A minor amount of nateglinide, together with its active metabolite, is excreted in the urine [152]. Therefore, in advanced CKD, nateglinide treatment still increases the risk of hypoglycemia.

### Glucagon-like peptide 1 agonists

The two main incretins secreted in the upper small intestine are glucagon-like peptide 1 (GLP-1) and glucose-dependent insulintropic peptide [119]. Gut hormones have been shown to play an important role in whole-body glucose homeostasis by suppressing meal-related glucagon secretion, delaying gastric emptying, and inducing satiety [152]. As the GLP-1 effect is diminished in type 2 diabetics, administration of exogenous GLP-1s (liraglutide, exenatide, and dulaglutide) is a therapeutic option [153]. Liraglutide is not excreted by the kidney [154]. Therefore dosing does not need any adjustment until the GFR value falls down below 30 mL/min. When GFR is lower than 30 mL/min/ $1.73\text{ m}^2$ , the drug is not contraindicated, but there is limited experience in this range of GFR. Liraglutide should not be prescribed in patients with eGFR  $<15\text{ mL/min/1.73 m}^2$  and during dialysis therapy [154]. In the LEADER trial, it was demonstrated that this drug decreased the mortality rate [155]. Another GLP-1 agonist exenatide is excreted by the kidneys. If GFR is higher than 50 mL/min, the dose does not need adjustment. Dose titration is recommended when GFR is in the range of 30–50 mL/min [153]. Dulaglutide dose adjustment is not necessary across the whole GFR range except below 30 mL/min [156]. This drug is now not recommended for use in CKD patients with GFR of less than 30 mL/min, mostly due to limited experience in this group of patients [156].

### Dipeptidyl-peptidase 4 inhibitors

The abovementioned incretins, including GLP-1, are rapidly degraded by the enzyme DPP-4. The effort to inhibit this enzyme led to the development of a new class of antiglycemic agents, DPP-4 inhibitors such as sitagliptin, linagliptin, and vildagliptin [151,157]. They pose no intrinsic risk of hypoglycemia. Sitagliptin is predominantly excreted in urine and accumulates in CKD patients. Despite precautions suggested by the manufacturer for CKD patients, the drug was generally well tolerated and effective in improving metabolic control of type 2 diabetes CKD patients [158]. Vildagliptin is also safe and effective in CKD, despite the fact that the drug is metabolized by the kidneys

and excreted in urine. When doses are reduced, they can still be used even in an advanced CKD [159]. The same applies for saxagliptin. DPP-4 inhibitors are considered to be safe and effective across all stages of CKD (includes patients treated with dialysis in which the dose should also be reduced) [157].

### Acarbose

Acarbose inhibits  $\alpha$ -glucosidase activity that leads to the inhibition of the hydrolysis of oligo-, di-, and trisaccharides to glucose and other monosaccharides. Therefore this drug reduced the postprandial increase in blood glucose [160]. The increased delivery of carbohydrates to the colon frequently causes side effects, for example, flatulence, bloating, abdominal pain, and diarrhea, rendering patient management difficult and reducing compliance [161]. In the context of renal impairment, acarbose in individuals with an eGFR less than 25 mL/min is not recommended [157].

### Sodium–glucose cotransporter type 2 inhibitors

Sodium–glucose cotransporter type 2 inhibitors (SGLT2i) reduce glucose tubular reabsorption and therefore induce glucosuria [162]. Moreover, these drugs by reducing sodium tubular reabsorption induce natriuresis [162,163]. Therefore SGLT2i act as diuretics. These drugs also decrease body weight and reduce blood pressure [164]. In most studies, it was shown that SGLT2i significantly decrease cardiovascular morbidity and mortality and all-cause mortality in type 2 diabetes patients [162–164]. Moreover, these drugs also disclose by nephroprotective properties [162]. SGLT2i activate the tubulo-glomerular feedback: the increased sodium load at *macula densa* triggers constriction of the afferent arteriole, thus reducing intraglomerular pressure and hyperfiltration. The treatment with SGLT2i should not be initiated in patients with GFR of less than 60 mL/min/ $1.73\text{ m}^2$  but might be continued till eGFR is over 45 mL/min/ $1.73\text{ m}^2$ . As was shown in DERIVE study, dapagliflozin was effective in the reduction of HbA1c, fasting blood glucose, body weight, and systolic blood pressure also in patients with eGFR ranging between 45 and 59 mL/min/ $1.73\text{ m}^2$  [165,166]. Moreover, it is worth to state that the major studies with SGLT2i: EMPA-REG (with empagliflozin) and CANVAS and CREDENCE (with canagliflozin) enrolled some patients with eGFR between 30 and 60 mL/min/ $1.73\text{ m}^2$  [167–170]. The Federal Drug Administration and European Medicines Agency have approved the continued use of canagliflozin in patients with a urinary albumin-to-creatinine ratio of 300 mg/g and eGFR less than 30 mL/min/ $1.73\text{ m}^2$  until renal replacement therapy [171].

## Insulin

The use of insulin, human or analogs, is recommended in type 2 diabetic patients with advanced CKD and severe uncontrolled hyperglycemia. Another more theoretical background is that in these catabolic patients the anabolic effect of insulin may be desirable. No clinical evidence is available to decide the optimal timing to start insulin treatment or which particular insulin regimen should be preferred in advanced CKD.

In recent years, a number of insulin analogs have been marketed. These newer insulins were developed by modifying the structure of the insulin molecule to alter the pharmacokinetic properties. Based on the data from a limited number of small studies, specific insulin analogs are effective and safe for patients with CKD [172,173]. The major side effects of insulin include weight gain and risk of hypoglycemia. Dose adjustments are often required to minimize the risk of hypoglycemia, especially with individuals on dialysis [146]. In patients without kidney disease and who are given subcutaneous exogenous insulin, up to 80% of insulin is cleared by the kidneys. As GFR falls below 20 mL/min, the kidneys are no longer able to efficiently clear insulin, resulting in prolonged insulin half-life and an increased potential for hypoglycemia [174]. The American College of Physicians recommended (1) a 25% decrease in the insulin dose when the GFR is decreased to between 50 and 10 mL/min and (2) a 50% decrease when GFR decreased below 10 mL/min [175]. In addition, once maintenance dialysis is initiated, the insulin resistance seen in CKD is often improved, resulting in reduced doses of insulin. Insulin requirements are often substantially decreased in anorectic patients with advanced CKD. Other factors that may contribute to changes in the need for exogenous insulin include reduction in renal gluconeogenesis, uremia-induced anorexia, and weight loss. In fact, one-third of the patients with type 2 diabetes no longer require insulin after 1 year of HD therapy [176]. Therefore, when these patients are treated with insulin, it is imperative to monitor blood glucose concentrations and to adjust the dose as needed to avoid hypoglycemia.

# Altered lipid metabolism and serum lipids in chronic kidney disease

Nosratola D. Vaziri<sup>1,2</sup>, Hamid Moradi<sup>1,3</sup> and Ying-Yong Zhao<sup>4</sup>

<sup>1</sup>Division of Nephrology, Hypertension and Kidney Transplantation, Department of Medicine, University of California, Irvine, CA, United States <sup>2</sup>Department of Medicine, Physiology and Biophysics, University of California, Irvine, CA, United States <sup>3</sup>Long Beach VA Healthcare System, Long Beach, CA, United States <sup>4</sup>School of Pharmacy, Faculty of Life Science & Medicine, Northwest University, Xi'an, P.R. China

The nonnephrotic chronic kidney disease (CKD) and end-stage renal disease (ESRD) results in marked reductions of lipoprotein lipase (LPL) and very-low-density lipoprotein (VLDL) receptor in skeletal muscle and adipose tissue, downregulation of hepatic lipase, LDL receptor-related protein (LRP), Apolipoprotein A1 (ApoA-1) and lecithin-cholesterol acyltransferase (LCAT) in the liver, upregulation of acyl-CoA cholesterol acyltransferase (ACAT) in the liver, renal, and arterial tissues, reduction of plasma high-density lipoprotein (HDL), oxidative modification of LDL and HDL, and impaired antioxidant, antiinflammatory, and reverse cholesterol transport capacities of HDL. Together these abnormalities lead to impaired clearance of chylomicrons and VLDL, accumulation of proinflammatory and atherogenic chylomicron and VLDL remnants, formation of small dense LDL, hypertriglyceridemia, and reduced availability of lipid fuel for energy production and storage. These events contribute to systemic inflammation, accelerated atherosclerosis, cachexia, and impaired exercise capacity. Plasma cholesterol is usually within or below the normal limits and only occasionally elevated in patients with ESRD or nonnephrotic CKD. This accounts for the reported failure of the randomized clinical trials of cholesterol-lowering agents to reduce the risk of adverse cardiovascular outcomes and overall mortality in hemodialysis patients.

## Introduction

During the last three decades the burden of CKD has dramatically increased worldwide, consuming a

disproportionate share of the health-care resources. CKD is associated with the triad of oxidative stress, inflammation, and dyslipidemia that are causally interconnected and form a vicious circuit that drives progression of kidney disease and promotes cardiovascular disease, cachexia syndrome, anemia, and many other complications. This chapter is intended to provide an overview of the features and mechanisms of CKD-associated dyslipidemia and its role in amplification of inflammation and oxidative stress, disturbance of energy metabolism, progression of renal disease, cardiovascular, and other complications.

## Plasma lipid and lipoprotein profile in chronic kidney disease/end-stage renal disease patients

Dyslipidemia in patients with nonnephrotic CKD and ESRD patients maintained on hemodialysis is characterized by hypertriglyceridemia, elevated plasma concentrations of VLDL, intermediate-density lipoprotein (IDL) and chylomicron remnants, accumulation of oxidized lipids and lipoproteins, and low plasma concentration of ApoA-1 and HDL cholesterol (HDL-chol) [1–6]. Unlike patients with heavy proteinuria who have hypercholesterolemia, serum-cholesterol and LDL-cholesterol values are frequently within or below the normal limits in the majority of hemodialysis-treated ESRD patients and CKD patients without nephrotic range proteinuria. In addition, LDL in these patients consists of highly atherogenic small dense particles that contain abnormal levels of residual triglycerides [7–10]. Finally, lipoprotein(a) [Lp(a)] plasma concentration

particularly its low-molecular forms is elevated and contributes to the risk of cardiovascular events in CKD and ESRD patients [11–14].

### **Conditions that modify lipid profile in chronic kidney disease/end-stage renal disease**

Several conditions significantly modify lipid profile in CKD or ESRD populations. These include dialysis modality (i.e., hemodialysis vs peritoneal dialysis), lipid-altering drugs (e.g., statins, fibrates, calcineurin inhibitors, steroids, and rapamycin), preexisting genetic disorders of lipid metabolism, and malnutrition and inflammation. In addition, by acting as a bile acid sequestrant, the commonly prescribed phosphate-binding resin, sevelamer, lowers plasma cholesterol concentration. Likewise, inflammation, which is a common feature of ESRD, can lower serum total cholesterol and further suppress HDL-chol levels. In contrast by simulating nephrotic syndrome [15,16], peritoneal dialysis, which results in substantial losses of proteins in the peritoneal dialysate effluent, can increase plasma LDL and total cholesterol concentrations. In addition, influx of large quantities of glucose from the peritoneal dialysis fluid can further raise plasma triglyceride levels in patients maintained on peritoneal dialysis.

## **The nature and mechanisms of chronic kidney disease—induced lipid abnormalities**

### **High-density lipoprotein metabolism and function**

HDL is a potent antioxidant, antiinflammatory, antithrombotic, and antiatherogenic component of the plasma. HDL protects against foam cell formation and atherosclerosis by promoting the efflux and preventing the influx of cholesterol in the macrophages in the artery wall. The combination of oxidative stress, structurally abnormal LDL, and the overabundance and prolonged plasma residence time of IDL and chylomicron remnants in CKD results in oxidation of LDL, lipoprotein remnants, and phospholipids. Once oxidized, these particles stimulate expression of scavenger receptors [e.g., oxidized LDL receptor-1 (LOX-1) and scavenger receptor A-1 (SRA-1)] in macrophages and resident cells in the artery wall. The scavenger receptors then engulf these oxidized lipids and lipoproteins, a process that is central to foam cell formation and atherosclerosis.

Normal HDL mitigates influx of lipids and lipoproteins in the macrophages by preventing or reversing lipid peroxidation via its potent antioxidant enzymes, that is, paraoxonase-1 (PON-1) and glutathione peroxidase (GPX). In addition, by raising endothelial production of nitric oxide and inhibiting release of chemokines, normal HDL limits monocyte adhesion and infiltration in the artery wall. Via these actions, normal HDL mitigates foam cell formation by limiting influx of cholesterol and

inhibiting migration of immune cells into the arterial vessel wall. The other important and well-known mechanism of antiatherogenic action of HDL is reverse cholesterol transport reverse cholesterol transport (RCT) that involves extraction of surplus cholesterol and phospholipids from the lipid-laden cells and their disposal in the liver. The HDL-mediated RCT involves the following steps: (1) binding of the nascent, cholesterol ester (CE)-poor HDL to the adenosine triphosphate (ATP)-binding cassette transporter A-1 (ABCA-1) that is the gateway of cholesterol efflux on the surface of the target cell. HDL binding to ABCA-1 triggers deesterification of intracellular CE leading to release of free cholesterol and its migration to the cell surface and from there to the surface of HDL. (2) Reesterification of free cholesterol on the surface of HDL by LCAT that is an essential component of HDL complex. Due to its hydrophobic property, CE moves into the core of HDL, a process that by sustaining a favorable concentration gradient maximizes the uptake of cellular cholesterol and maturation of HDL to a CE-rich spherical particle. (3) Once matured, HDL detaches from the cell surface and travels to the liver where it binds to the scavenger receptor B-1 (SRB-1) that is expressed on the hepatocytes and serves as a docking receptor for the mature HDL. Binding to SRB-1 facilitates disposal of the HDL's CE cargo in the liver and clearance of its phospholipid and triglyceride by hepatic lipase. Once emptied, HDL detaches from hepatocyte and is released into the circulation. In contrast to the CE-rich HDL, CE-poor HDL particles have low affinity for SRB-1 and a high affinity for binding to the endocytic receptor (ATP synthase beta) that is expressed on hepatocytes and mediates removal and degradation of these particles [17].

### **Effect of chronic kidney disease on structure and function of high-density lipoprotein**

As described in comprehensive reviews [5,18], CKD has a profoundly negative effect on the concentration, structure and antioxidant, antiinflammatory, and reverse cholesterol transport activities of HDL [19–23]. This is primarily due to (1) downregulation of hepatic biosynthesis and reduced plasma level of ApoA-1 that is the main protein component of HDL, the ligand for the HDL's loading and unloading receptors (ABCA-1 and SRB-1, respectively), and the principal carrier of HDL's lipid cargo [23–25]. The deficiency of ApoA-1 plays an important part in HDL deficiency and dysfunction in CKD. (2) The other important cause of CKD-associated HDL deficiency and dysfunction is reduced plasma concentration and enzymatic activity of LCAT that is due to the CKD-induced reduction of its hepatic production [26,27] and urinary losses in nephrotic syndrome [28]. The acquired LCAT deficiency in CKD plays a major role for the depressed HDL-mediated RCT, impaired HDL maturation, and reduced plasma HDL-chol, which

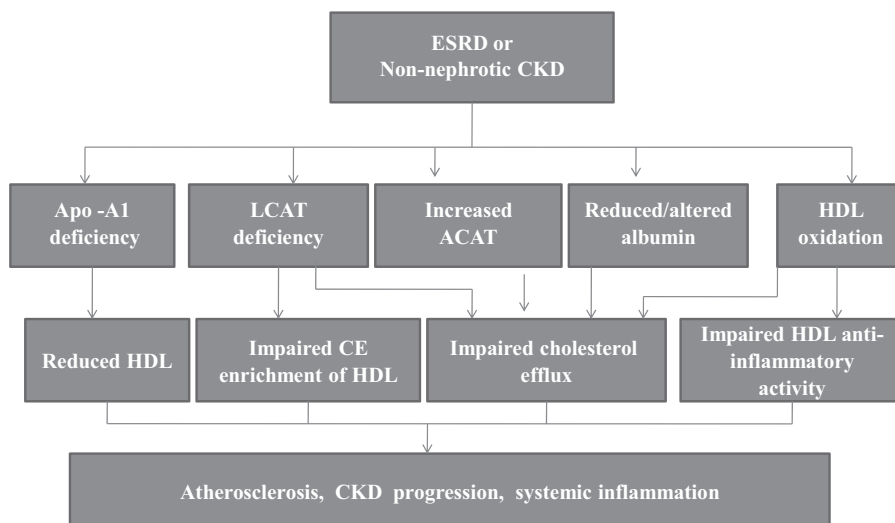

collectively contribute to the atherogenic diathesis in this population. (3) CKD results in diminished plasma activity and concentration of paraoxonase and GPX [21,23] and elevation of myeloperoxidase [29], which contribute to the reduction of antioxidant capacity of HDL, thereby limiting its ability to prevent/reverse oxidation of LDL and remnant lipoproteins. Moreover, deficiency of the HDL's antioxidant enzymes heightens susceptibility of ApoA-1 to oxidative modification that limits the binding affinity of HDL to ABCA-1 and, thereby, negatively affects RCT [30]. (4) CKD results in diminished antiinflammatory capacity of HDL [4,5] that normally protects against plaque formation by raising nitric oxide production and inhibiting endothelial cell activation and monocyte adhesion and infiltration. (5) When present, nephrotic proteinuria results in marked reduction of hepatic HDL docking receptor (SRB-1) protein abundance, but not its transcript [31]. This can interfere with the HDL-mediated RCT by limiting disposal of HDL's cholesterol cargo. The observed reduction in hepatic SRB-1 protein abundance is due to downregulation of the adapter molecule, PDZ domain containing 1, which is essential for the transport and anchoring of the receptor to the hepatocyte plasma membrane [29]. (6) Deficiency of the hepatic HDL docking receptor, SRB-1, is compounded by upregulation of HDL endocytic receptor (beta chain ATP synthase) in CKD with, but not without, heavy proteinuria [30,31]. This can contribute to the HDL deficiency by raising its catabolism. (7) Oxidative modification of HDL that diminishes its ability to promote cholesterol efflux by limiting its binding affinity for ABCA-1 [29]. (8) Apolipoprotein M (ApoM) is another HDL-bound apolipoprotein that plays a role in the pre-Beta-HDL formation and facilitates cholesterol efflux from macrophages [32]. Plasma ApoM level is

reduced and its deficiency contributes to cardiovascular complications in patients with advanced CKD [33]. (9) The HDL content of plasmalogens (belonging to the phospholipids family) that enhance the antiapoptotic and antiatherogenic properties and cholesterol efflux capacity of HDL are reduced in ESRD patients [34]. And finally, (10) hypoalbuminemia that is common in patients with advanced CKD contributes to the reduction of HDL-chol. This is because albumin shuttles substantial amounts of free cholesterol from the peripheral tissues to the circulating cholesterol-poor HDL particles and as such when present, hypoalbuminemia impairs reverse cholesterol transport [35].

It should be noted that the rates of cholesterol extraction from peripheral tissues and its disposal in the liver by HDL determine serum concentration of HDL-chol and its protective properties. Therefore both impaired cholesterol uptake that is marked by low HDL-chol concentration and impaired unloading of HDL-chol cargo in the liver that is marked by abnormal elevation of HDL-chol concentration increase the risk of cardiovascular and other complications. In fact, Chang et al. [36] found a significant increase in mortality among subpopulation of ESRD patients whose HDL-chol levels exceeded 60 mg/dL. This finding indicated that impaired capacity of HDL to unload its cholesterol cargo results in elevated HDL-chol and increased cardiovascular morbidity/mortality in a subpopulation of ESRD patients.

Together the abnormalities of metabolism, structure, and function of HDL contribute to the prevailing systemic inflammation and cardiovascular disease in the CKD population. The effects of CKD and ESRD on HDL metabolism and its adverse consequences are summarized in Fig. 4.1.

### Effects of non-nephrotic CKD or ESRD on HDL metabolism

**FIGURE 4.1** The nonnephrotic CKD or ESRD results in diminished production and depressed plasma levels of ApoA-1 and LCAT, upregulation of ACAT, reduced plasma concentration and structural modification of albumin, and oxidative modification of HDL. These events lead to reduced HDL cholesterol, impaired antioxidant, antiinflammatory, and reverse cholesterol transport capacities of HDL, which collectively promote atherosclerosis, systemic inflammation, and CKD progression. ACAT, Acyl-CoA cholesterol acyltransferase; ApoA-1, apolipoprotein A1; CKD, chronic kidney disease; ESRD, end-stage renal disease; HDL, high-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase.

### Effects of chronic kidney disease on very-low-density lipoprotein and chylomicron metabolism

VLDL and chylomicron are triglyceride-rich lipoproteins that deliver endogenous and dietary lipid fuels and construction material to the myocytes, adipocytes, and other cell types for production and storage of energy and incorporation in the cellular structures. Metabolism of VLDL and chylomicrons is markedly impaired in CKD. The nascent VLDL particles are assembled in the liver and nascent chylomicrons are packaged in the intestinal epithelial cells and released into the circulation. Once released into the circulation, the nascent VLDL and chylomicrons receive apolipoprotein E (ApoE) and apolipoprotein C (ApoC) from cholesterol-rich HDL-2 particles. Acquisition of ApoE and ApoC is essential for maturation and subsequent clearance of VLDL and chylomicrons in the peripheral tissues. However, scarcity of CE-rich HDL (caused by LCAT deficiency) in CKD severely impedes this essential process. Normally, chylomicrons and VLDL bind to the endothelial surface of the capillaries perfusing muscles and adipose tissues via ApoE and activate endothelial-bound LPL via ApoC-2. Once activated, LPL hydrolyzes the triglyceride contents of these particles. This leads to release of over 70% of free fatty acid contents of these particles for uptake by myocytes and adipocytes. The particles are then released into the circulation as VLDL remnants (also known as IDL) and chylomicron remnants. CKD results in significant reduction of LPL abundance and activity in skeletal muscle, adipose tissue, and myocardium [37–39]. This is accompanied by downregulation of the endothelium-derived adapter molecule, glycosylphosphatidylinositol-anchored binding protein 1 (GPIHBP1), which plays a critical role in LPL metabolism and function by anchoring LPL on the endothelium and binding chylomicrons [40]. Consequently, deficiencies of LPL and its adapter molecule, GPIHBP1, in CKD severely impair metabolism of VLDL and chylomicrons.

Chylomicron remnants and a portion of IDL are cleared from the circulation by LRP that is a large multifunctional endocytic receptor expressed in hepatocytes [41]. A study found significant downregulation of hepatic LRP in animals with CKD [42]. Given the central role of LRP in removing chylomicron remnants, its deficiency contributes to elevated plasma levels of these oxidation-prone atherogenic particles in CKD.

Under normal condition the great majority of IDLs are converted to LDL that is a CE-rich lipoprotein and is avidly cleared by the liver via LDL receptor. The transformation of IDL to LDL requires the removal of triglyceride cargo and CE enrichment of IDL. These events are catalyzed by CE transfer protein (CETP) and hepatic lipase. CETP mediates exchange of triglycerides

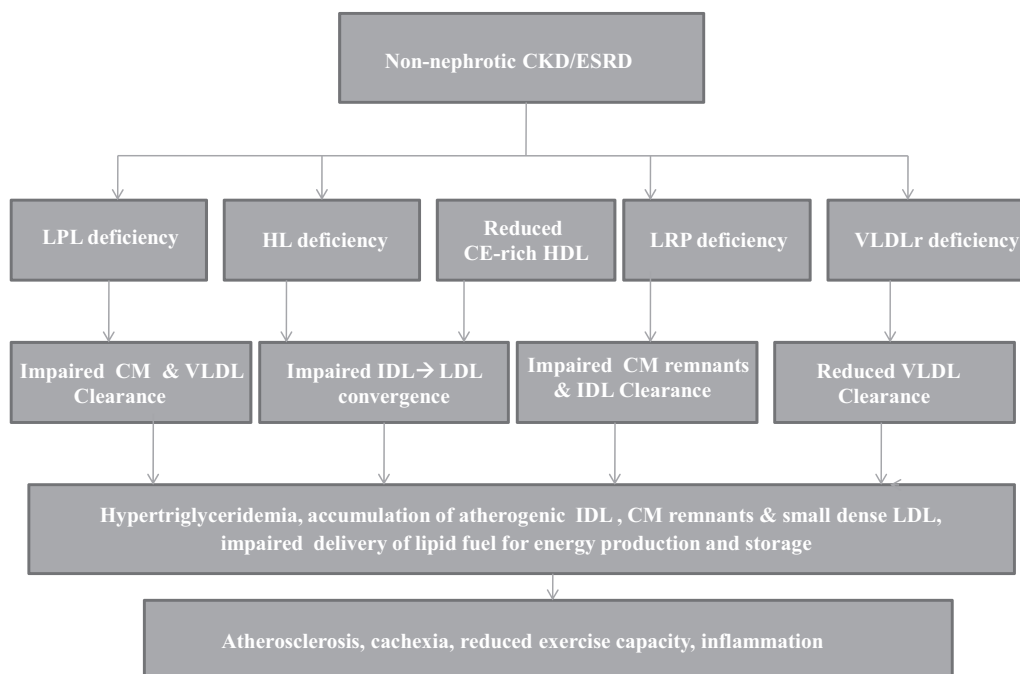

for CE between IDL and CE-rich HDL2 particles and hepatic lipase catalyzes hydrolysis of the triglyceride and phospholipid contents of IDL. Although plasma CETP activity and concentration are normal in ESRD [43], the scarcity of CE-rich HDL limits the ability of CETP to fulfill its normal function. Moreover, CKD is associated with downregulation of hepatic lipase [44–46] that contributes to accumulation of IDL and formation of CE-poor, triglyceride containing small dense LDL. These abnormal LDL particles are highly oxidation prone and atherogenic and have low binding affinity for LDL receptor. Normally, a fraction of VLDL is cleared from the circulation via endocytosis by VLDL receptor that is expressed by myocytes and adipocytes [47]. A study in experimental animal model of CKD revealed significant downregulation of VLDL receptor expression in the skeletal muscle and adipose tissues [48,49]. This abnormality can potentially contribute to elevation of plasma VLDL and hypertriglyceridemia and thus compound the effects of LPL, hepatic lipase and LRP deficiencies, and impaired HDL maturation on VLDL and IDL metabolism in CKD. The effect of non-nephrotic advanced CKD or ESRD on metabolism of triglyceride-rich lipoproteins and its adverse consequences are summarized in Fig. 4.2.

### Effect of chronic kidney disease on cholesterol metabolism

As mentioned earlier, plasma total cholesterol and LDL-cholesterol levels are frequently within or below the normal limits in most nonnephrotic CKD and ESRD patients receiving hemodialysis therapy. In addition, HMG-CoA reductase expression and activity are normal in the liver of animals with nonnephrotic CKD, induced by subtotal nephrectomy [50]. Moreover, hepatic expression of LDL receptor, HDL docking receptor and activity of the cholesterol 7- $\alpha$  hydroxylase, the enzyme responsible for conversion of cholesterol to bile acids are normal in CKD animals [51]. Despite having normal or subnormal plasma cholesterol and LDL-cholesterol levels and presumably normal cholesterol biosynthesis and cholesterol clearing capacities, the risk of atherosclerosis and cardiovascular disease is greatly increased in CKD patients. In fact, CKD animals exhibit accumulation of cholesterol in the artery wall and remnant kidney [51,52]. This is associated with and driven by oxidation of lipids and lipoproteins, upregulation of SRA-1 and LOX-1, and ACAT, the enzyme responsible for intracellular sequestration of CE and foam cell formation in the artery wall and diseased kidney [53–56]. These observations illustrate the critical role of oxidative stress and inflammation as opposed to elevated

### Effects of non-nephrotic CKD or ESRD on triglyceride-rich lipoprotein metabolism

**FIGURE 4.2** The nonnephrotic CKD or ESRD results in downregulation of skeletal muscle, adipose tissue, and myocardial LPL and VLDLr, HL, LRP and marked reduction of plasma CE-rich HDL. Together these abnormalities lead to impaired clearance of chylomicrons and VLDL, accumulation of oxidation-prone atherogenic chylomicron remnants and IDL, formation of small dense LDL, increased plasma triglyceride concentration, and reduced delivery of lipid fuel for energy production in myocytes and storage in adipocytes. Accumulation of the atherogenic chylomicron remnants and IDL and formation of small dense LDL promote atherosclerosis and systemic inflammation whereas reduced LPL- and VLDL receptor-mediated delivery of lipid fuel contributes to cachexia and reduced exercise capacity. *CE*, Cholesterol ester; *CKD*, chronic kidney disease; *ESRD*, end-stage renal disease; *HDL*, high-density lipoprotein; *HL*, hepatic lipase; *IDL*, intermediate-density lipoprotein; *LDL*, low-density lipoprotein; *LPL*, lipoprotein lipase; *LRP*, LDL receptor-related protein; *VLDL*, very-low-density lipoprotein; *VLDLr*, VLDL receptor.

plasma cholesterol or increased cholesterol biosynthesis as the cause of atherosclerosis in CKD. It is, therefore, not surprising that as described in the section on clinical trials, statins have proven ineffective in lowering the incidence of cardiovascular disease in the majority of ESRD patients maintained on hemodialysis. However, when present, preexisting hereditary hypercholesterolemia and nephrotic proteinuria compound the effect of renal insufficiency and cause hypercholesterolemia by raising cholesterol biosynthesis (upregulation of HMG-CoA reductase) and limiting cholesterol clearance (inducing LDL receptor and HDL docking receptor deficiencies).

### The nature and mechanisms of adverse effects of lipid disorders in chronic kidney disease

Alterations of lipid metabolism have far-reaching consequences and contribute to numerous CKD-associated disorders and complications [53,57]. Some of these effects are briefly described in the following sections.

### Inflammation and oxidative stress

As noted earlier, the CKD-induced constellation of LPL, hepatic lipase and LRP deficiencies, and impaired HDL function results in extended residence time and accumulation of IDL and chylomicron remnants in the plasma and formation of small dense LDL. The IDL, chylomicron remnants, and small dense LDL particles are exquisitely susceptible to oxidation, a phenomenon that is amplified by the prevailing oxidative stress and HDL deficiency/dysfunction in the CKD population. In fact, plasma concentration of oxidized LDL and lipid peroxidation products is markedly increased in patients and animals with CKD. Oxidized LDL and remnant particles promote inflammation by avidly binding LOX-1, SRA-1, and oxidized phospholipid receptors on monocytes and macrophages, thereby triggering release of proinflammatory cytokines. Riding in the circulating blood these particles can disseminate inflammation throughout the body. Likewise, through lipid peroxidation chain reaction, oxidized lipoproteins contribute to dissemination and amplification of oxidative stress that is a constant feature of CKD. Accordingly, dysregulation

of lipid metabolism in CKD plays a part in the pathogenesis of systemic inflammation and oxidative stress that are constant features and major mediators of progression of CKD and its cardiovascular and many other complications [54].

### ***Atherosclerosis and cardiovascular disease***

CKD results in accelerated atherosclerosis and cardiovascular disease that are the main causes of death in this population [58–60]. In addition to the classic atherosclerosis, several other conditions contribute to cardiovascular disease in the CKD/ESRD population. These include arteriosclerosis, which is marked by stiffening of the arteries, endothelial dysfunction, vascular calcification, myocardial fibrosis, cardiomyocyte/capillary mismatch, dilated cardiomyopathy, and sudden cardiac death [61–65]. These disorders are mediated by hypertension, hypervolemia, phosphate retention, reduced nitric oxide availability (caused by oxidative stress and accumulation of NO synthase inhibitor, asymmetrical dimethylarginine), electrolyte abnormalities, myocardial fibrosis and ischemia (triggering arrhythmias), and drug toxicities, among other conditions. Atherosclerosis in CKD is primarily driven by the prevailing inflammation and oxidative stress [66,67] as opposed to elevated plasma cholesterol concentration or low HDL-chol level. In fact, observational studies have shown an association between low plasma cholesterol and highly elevated HDL-chol with increased risk of cardiovascular and overall mortality in ESRD population and a greater survival in those with higher serum total and LDL-cholesterol values [8,68]. It should be noted, however, that the association between higher plasma cholesterol levels with a lower mortality in ESRD patients is most likely related to the cholesterol-lowering action of systemic inflammation as opposed to the salutary effect of high-cholesterol concentrations.

Although elevated cholesterol in patients with familial hypercholesterolemia, chronic nephrotic syndrome, high dietary cholesterol, or other causes can lead to atherosclerosis and cardiovascular disease, accelerated atherosclerosis frequently occurs in the absence of hypercholesterolemia in patients with type 2 diabetes and patients with CKD and ESRD. This is not surprising since relatively small amounts of cholesterol are sufficient to form plaques capable of causing serious cardiovascular events by occluding coronary, cerebral, or peripheral arteries. Therefore disorders that increase influx and/or impair efflux of cholesterol in the macrophages can cause atherosclerosis and cardiovascular disease even when plasma cholesterol is within or below the normal limits. This is clearly illustrated by the failure of the cholesterol-lowering strategies to lower cardiovascular events in the randomized clinical trial of various statins in ESRD patients

maintained on hemodialysis [69–71]. The primary mechanism of accelerated atherosclerosis in CKD/ESRD patients is most likely the oxidation of small dense LDL, chylomicron remnants and IDL, and their avid uptake by macrophages. The increased cholesterol influx is compounded by HDL deficiency and dysfunction, which limit reverse cholesterol transport in CKD. Consequently, the atherogenic process in highly inflamed CKD patients proceeds relentlessly regardless of plasma cholesterol level and despite the use of cholesterol-lowering agents.

### ***Lipotoxicity and its role in progression of kidney disease***

The prevailing oxidative stress in CKD results in accumulation of oxidized lipids and other compounds in the body fluids and tissues [72–77]. Macrophages and mesangial cells in the diseased kidney avidly engulf oxidized lipids and lipoproteins [77]. Accumulation of lipid in the renal tissue can promote progression of glomerular and tubulointerstitial lesions in metabolic syndrome and in chronic glomerular diseases [73,77–80]. In fact, progression of renal disease in the animals with CKD induced by subtotal nephrectomy is accompanied by heavy accumulation of lipids in the glomeruli and proximal tubular epithelial cells and in the artery wall [52] and accumulation of lipids in the nonadipose tissues can cause cellular injury and dysfunction [81] as seen in hepatic steatosis and atherosclerosis. Cellular lipid homeostasis is regulated by the balance between influx, efflux, synthesis, and catabolism of lipids. An imbalance in these pathways can result in lipid accumulation in macrophages, mesangial cells, vascular smooth muscle cells (VSMCs), and other cell types causing tissue damage. Influx of lipids into macrophages and mesangial cells is mediated by a number of receptors, including scavenger receptor class A (SRA-1), class B (CD36), and class E (LOX-1) [78,79]. Lipid accumulation in the wall of the aorta and remnant kidney in 5/6 nephrectomized rats is accompanied by marked upregulation of SRA-1 and LOX-1 [51,52], pointing to increased lipid influx in these tissues. Oxidized LDL and inflammatory cytokines stimulate expression of these receptors. This illustrates the causal link between oxidative stress and inflammation with accumulation of lipids in the macrophages and VSMCs in the artery wall and in the macrophages and mesangial cells in the renal tissue in CKD animals.

The development of glomerulosclerosis and progression of kidney disease is associated with proteinuria. Proximal tubular epithelial cells reabsorb filtered proteins, including lipid-carrying proteins such as albumin and ApoA-1 via megalin–cubilin complexes expressed on their apical membrane [79,80]. Glomerular proteinuria markedly increases the burden of reabsorbed

filtered proteins and their lipid cargo causing expansion of the intracellular lipid pool in proximal tubular epithelial cells. In addition, interaction of protein-bound lipids with megalin–cubilin complexes activates several signal transduction pathways that trigger cellular apoptosis and release of proinflammatory and profibrotic mediators and thereby contributes to tubular atrophy, interstitial fibrosis, and inflammation [82]. In fact, proteinuria, glomerulosclerosis, tubulointerstitial fibrosis, inflammation, and accumulation of lipids in the proximal tubular epithelial cells in the remnant kidneys of rats 12 weeks after 5/6 nephrectomy were associated with marked upregulation of megalin–cubilin complexes [52]. These findings demonstrate the role of proteinuria in accumulation of lipid in the proximal tubules and the potential lipid-mediated tubular injury and interstitial inflammation and fibrosis.

Studies of the cholesterol efflux pathway in the remnant kidney tissue and artery wall have shown upregulation of ABCA-1 and activation of its upstream transcription factor, liver X receptor that is an intracellular sterol-sensing molecule [51,52]. This phenomenon represents the cellular response to elevated cholesterol burden in the arterial and remnant kidney tissues in CKD. The success of the upregulation of cellular cholesterol efflux pathway in unloading of the surplus cholesterol depends on HDL-mediated uptake and disposal of the lipid cargo. However, HDL-mediated reverse cholesterol transport is severely impaired in CKD. Several factors contribute to the reduction of HDL-mediated reverse cholesterol transport in CKD. These include diminished hepatic production and plasma concentration of ApoA-1 and LCAT as well as oxidative modification of HDL that can compromise the critical interaction between HDL and ABCA-1.

Studies of the *de novo* lipid biosynthesis have revealed marked suppression of cholesterol production machinery in the diseased kidney [52]. These findings substantiate excessive influx and impaired HDL-mediated efflux as opposed to increased local production as the cause of cholesterol accumulation in the renal tissue. However, fatty acid production machinery is upregulated and peroxisome proliferator–activated receptor (PPAR)- $\alpha$ -driven fatty acid catabolism is suppressed in the diseased kidney [52]. Upregulation of the fatty acid production system in the remnant kidney is driven by activation of carbohydrate response element-binding protein (ChREBP) that is an intracellular sensor of glucose. The activation of ChREBP and consequent increase in fatty acid synthesis in the remnant/diseased kidney is most likely driven by increased filtered glucose load per nephron occasioned by increased single-nephron glomerular filtration rate (GFR).

Activity of PPAR- $\alpha$  that is the master regulator of fatty acid catabolism is markedly reduced in the

remnant/diseased kidney. In the normal kidney, PPAR- $\alpha$  is heavily expressed in the proximal tubules and medullary thick ascending limb of loop of Henle and is weakly expressed in mesangial cells [82]. PPAR- $\alpha$  regulates expression of genes involved in fatty acid catabolism, including liver type fatty acid-binding protein (L-FABP) and acyl-CoA oxidase (ACO). These proteins play a critical part in mitochondrial and peroxisomal beta oxidation of fatty acids. Earlier studies revealed significant downregulation of PPAR- $\alpha$  activity (nuclear translocation) and its target genes, L-FABP and ACO in the remnant kidneys of rats with CKD [52,83]. These findings unraveled yet another mechanism that contributes to increased lipid burden and lipotoxicity in the diseased kidney. Accordingly, increased production and depressed catabolism of fatty acids along with heightened influx and impaired efflux of cholesterol and neutral lipids contribute to accumulation of lipids in the diseased kidney. This is accompanied by significant upregulation of the enzyme ACAT1 that catalyzes esterification of cholesterol and sequestration of CEs in intracellular vesicles, a process that impedes HDL-mediated cholesterol efflux and leads to foam cell transformation [52]. In fact, a study demonstrated that administration of an ACAT inhibitor can ameliorate proteinuria and preserve residual renal function in this model [84] pointing to the role of ACAT in progression of renal disease.

There is little evidence that hyperlipidemia *per se* can cause kidney disease in the absence of preexisting renal disease or conditions that cause kidney disease. However, when present, hyperlipidemia can accelerate progression of preexisting renal disease and amplify the effect of conditions that can induce kidney disease. For instance, consumption of a high-cholesterol diet augments the development of glomerulosclerosis in rats with unilateral nephrectomy [85]. Similarly, induction of hypercholesterolemia with high-cholesterol diet increases the severity of proteinuria and glomerular lipid deposition in rats with CKD induced by subtotal nephrectomy [85]. Moreover, lipid-lowering strategies ameliorate renal injury in several animal models of CKD. For instance, administration of lovastatin has been shown to attenuate glomerular injury and albuminuria in Dahl salt-sensitive rats consuming high salt diet [86]. Likewise, administration of antihypertensive and cholesterol-lowering agents attenuated severity of histological lesions and the associated proteinuria in rats with nephrotoxic serum nephritis [87]. The salutary effects of lipid-lowering interventions in most animal models of CKD are associated with the reduction of inflammatory cell infiltration, fibrosis, and expression of proinflammatory and profibrotic mediators and consistently observed in different models of renal injury [88–91].

## Nutrition and energy metabolism

In addition to causing hypertriglyceridemia and contributing to amplification of oxidative stress, inflammation, and cardiovascular disease, defective clearance of triglyceride-rich lipoproteins leads to impaired energy metabolism, reduced exercise capacity, cachexia, and malnutrition syndrome in patients with advanced CKD. By limiting the delivery of lipids to the adipocytes and myocytes, downregulation of LPL and VLDL receptor limits the availability of lipid fuel and construction material to the skeletal muscles and myocardium and adipose tissues in CKD [49]. This abnormality deprives the skeletal muscle and myocardium from free supplies of lipid fuel and as such can contribute to muscle weakness and myocardial dysfunction. Likewise, diminished delivery of fatty acids to the adipose tissue limits the long-term energy storage capacity and contributes to weight loss and cachexia in ESKD patients.

## Treatment of chronic kidney disease—associated dyslipidemia

In light of the role of dyslipidemia in progression of CKD and the associated cardiovascular complications, interventions aimed at improving lipid metabolism can be important in the management of patients with CKD. A brief description of the available data on the efficacy of the currently available lipid-modulating drugs in the treatment of CKD-induced dyslipidemia is provided in the following sections.

### ***Statins in primary prevention of cardiovascular disease in end-stage renal disease patients***

Three large prospective randomized controlled clinical trials were conducted to address the efficacy of statin therapy in lowering the risk of cardiovascular mortality in ESKD patients maintained on hemodialysis. The first of these trials was the 4D (Die Deutsche Diabetes Dialyse) study [69] that enrolled 1255 hemodialysis patients with type 2 diabetes randomized to atorvastatin, 20 mg/d or placebo for 4 years. The study despite a significant decrease in serum LDL-cholesterol level showed no significant reduction of the risk of death from cardiac causes, nonfatal myocardial infarction (MI), and instead revealed a significant increase in the risk of a fatal stroke (95% CI 1.05–3.93) in the statin-treated group.

The second large trial termed “An assessment of Survival and Cardiovascular Events (AURORA)” was a double-blind, randomized, placebo-controlled, multicenter trial undertaken to compare the effect of rosuvastatin 10 mg/d versus placebo on cardiovascular morbidity and mortality in ESRD patients maintained

on regular hemodialysis treatment [70]. A large number (2776) of patients 50–80 years of age on dialysis for at least 3 months were enrolled in this study from 25 countries. The primary endpoint was major cardiovascular events, including fatal and nonfatal MI and stroke; the secondary endpoints included all-cause mortality, revascularization, and death from cardiovascular and noncardiovascular causes; and the tertiary endpoints included changes in the baseline lipids and high-sensitivity C-reactive protein (hs-CRP). The mean baseline LDL-cholesterol values in the rosuvastatin (100 mg/dL) and placebo (99 mg/dL) groups were nearly identical. The mean duration of treatment and the mean length of follow-up were 2.4 and 3.2 years, respectively. A total of 1296 patients died, and 810 patients discontinued the treatment because of adverse drug reactions or renal transplantation during the study period. The LDL-cholesterol concentration fell by approximately 43% and hs-CRP decreased by 11.5% in the rosuvastatin group within the first year of the trial. However, despite marked reduction of cholesterol level in the rosuvastatin-treated group, no significant difference was observed in either mortality or primary or secondary endpoints between the two groups. Moreover, a significant increase in the rate of fatal hemorrhagic stroke was found in the rosuvastatin-treated patients with diabetes ( $P = .03$ ), confirming the results of the 4D trial.

The third and the largest randomized primary prevention statin trial in CKD patients was the Study of Heart and Renal Protection (SHARP) [71]. This study differed from the 4D and AURORA trials since in addition to the dialysis patients it included a large cohort of CKD patients who did not require dialysis. A total of 9270 patients (3023 ESRD patients on maintenance dialysis and 6247 CKD patients not requiring dialysis) without history of MI or coronary revascularization were enrolled in this study. Patients were randomly assigned to receive simvastatin 20 mg/d with or without ezetimibe 10 mg/d or placebo. The median duration of follow-up was 4.9 years. Mean baseline LDL-cholesterol levels were 108 mg/dL in the entire group and 100 mg/dL in the dialysis subgroup. It was lowered by 30 mg/dL with simvastatin alone and by 43 mg/dL with simvastatin plus ezetimibe at 1 year. The study sought to investigate effectiveness of LDL-cholesterol reduction on major vascular events and the rate of progression of CKD in as yet dialysis-independent patients. The estimated GFR (eGFR) in the CKD groups averaged 27 mL/min/1.73 m<sup>2</sup>. The primary endpoints were the occurrence of a major atherosclerotic event that included death due to coronary disease, MI, nonhemorrhagic stroke, or the need for revascularization procedures. The study revealed 17% reduction in major atherosclerotic events (relative risk

0.83; 95% CI 0.74, 0.94; log rank  $P = .002$ ), 25% reduction in nonhemorrhagic stroke, 21% reduction in coronary revascularization, and a trend toward reduction in nonfatal MI in the entire simvastatin- and ezetimibe-treated arm. It should be noted, however, that cholesterol-lowering therapy did not significantly reduce either mortality rates or cardiovascular events in the dialysis-dependent ESRD patients enrolled in the SHARP trial. Therefore the results of the SHARP trial confirmed those of AURORA and 4D studies and the only reason for the salutary results reported for the entire enrolled population was the fact that the SHARP trial was weighted toward patients with less advanced CKD, in whom the underlying mechanisms of cardiovascular disease are more akin to that in the general population.

Holdaas et al. [92] conducted a multicenter, randomized, placebo-controlled trial in 2102 renal transplant recipients in which participants were randomly assigned to receive fluvastatin or placebo. The primary endpoint included major cardiac events (cardiac death, nonfatal MI, or coronary interventions). After an average follow-up of 5 years, fluvastatin significantly reduced serum LDL-cholesterol concentration by 32%. Although there were significantly fewer cardiac deaths or nonfatal MI [70 vs 104, 0.65 (0.48–0.88)  $P = .005$ ] in the fluvastatin group than in the placebo group, the risk reduction for the primary endpoint [risk ratio 0.83 (95% CI 0.64–1.06),  $P = .139$ ] did not reach statistical significance. Likewise, the incidence of coronary intervention procedures and other secondary endpoints were not significantly different between the fluvastatin and placebo-treated groups.

The negative results observed in trials of statins in hemodialysis patients contrast their salutary effects in reducing the risk of cardiovascular events in the general population [93]. As noted earlier, plasma cholesterol is within or below the normal limits in the majority of ESKD patients maintained on hemodialysis and the atherosclerosis and cardiovascular diseases in this population are primarily driven by oxidative stress, inflammation, HDL deficiency and dysfunction, impaired clearance of VLDL and chylomicrons, accumulation of IDL and chylomicron remnants, and formation of atherogenic small dense LDL. Since these abnormalities are not amenable to statin therapy, it is not surprising that treatment with these agents does not reduce the risk of cardiovascular disease in this population. However, when present, hypercholesterolemia can compound the risk of cardiovascular disease in this population in whom statin therapy can have salutary effects. This supposition was confirmed by a post hoc analysis of the 4D study [94] that demonstrated that atorvastatin significantly reduced the rates of adverse cardiovascular and overall outcomes in

patients with the highest quartile of baseline LDL cholesterol ( $\geq 145$  mg/dL, 3.76 mmol/L). No such benefit was observed in patients with the other quartiles of LDL-cholesterol at baseline. Consequently, it is possible that statin therapy is effective in hemodialysis patients with elevated serum LDL-cholesterol concentrations.

### ***Statins in primary prevention of cardiovascular disease in nondialysis chronic kidney disease patients***

Data derived from subgroup analysis of the secondary prevention trials have suggested that statins may lower the risk of adverse cardiovascular outcomes in patients with stages I–IV CKD [95]. Likewise, meta-analysis of data on 18,176 patients with CKD stages I–IV derived from five different studies showed a significant reduction (0.81) of the relative risk of all-cause mortality with statin therapy [96]. The prospective randomized trial designed to evaluate efficacy of statins in patients with mild CKD called “Prevention of Renal and Vascular Endstage Disease Intervention Trial” (PREVENT IT study) [97] enrolled 864 patients with microalbuminuria. The patients were randomized to fosinopril 20 mg/d, pravastatin 40 mg/d, or matching placebos and followed for 4 years. The study showed an insignificant reduction in the cardiovascular mortality and hospitalization for cardiovascular morbidity in the pravastatin-treated group. The reason for the disparity in response to statin therapy between the PREVENT IT study and the former two studies is unclear. One possible explanation is the difference in the magnitude of proteinuria among the study populations. Heavy proteinuria is frequently associated with hypercholesterolemia and increased risk of cardiovascular disease. Hypercholesterolemia in this condition is due to downregulation of hepatic LDL receptor and HDL docking receptor, which results in increased hepatic HMG-CoA reductase activity and cholesterol synthesis [15,31,98]. Therefore pharmacological inhibition of HMG-CoA reductase with statins in such cases can have salutary effect. Patients enrolled in the PREVENT IT study had microalbuminuria, whereas patients included in the former studies had stages I–IV CKD that usually encompasses a significant subset of patients with significant proteinuria who might benefit from statin treatment. In this context, ESKD patients maintained on chronic peritoneal dialysis experience significant daily losses of proteins in their peritoneal dialysate effluent that can cause hypercholesterolemia simulating nephrotic syndrome in functionally anephric individuals. Unlike the majority of hemodialysis patients who have normal or subnormal plasma cholesterol, majority of peritoneal dialysis

patients have hypercholesterolemia [98] and may benefit from statin therapy.

### ***Effect of statins on progression of kidney disease***

The available data on the effect of statins on progression of kidney disease are primarily derived from secondary or post hoc analysis of the secondary prevention studies and a limited number of randomized clinical trials that have directly addressed this issue. The former studies were primarily conducted to determine the effect of statins on cardiovascular outcomes in patients with either preexisting heart disease or those at high risk of developing cardiac disease. Among these studies the Heart Protection trial showed a significantly lower rate of decline in GFR in simvastatin-treated compared to placebo-treated groups [99]. The post hoc analysis of data from GREACE (Greek Atorvastatin and Coronary-heart-disease Evaluation) study that compared atorvastatin with usual care in patients with coronary artery disease showed an approximately 5% decline in eGFR in untreated patients with dyslipidemia and coronary disease and normal renal function at baseline during the 3-year study period. Treatment with statin prevented the decline in estimated GFR and in fact resulted in an approximately 5% increase in eGFR in the treated arm [100]. The salutary effect of statin on renal function was more pronounced in the lower two quartiles of baseline GFR and with higher atorvastatin doses. The subgroup analysis of the CARE trial showed that pravastatin significantly slowed the rate of the decline in GFR by 2.5 mL/min/year in patients with GFR below 40 mL/min/1.73 m<sup>2</sup>, but not in the study population as a whole [101]. The subanalysis of data from the "Treatment to New Targets" study in patients with coronary heart disease [102] revealed a significant improvement in estimated GFR over the 5-year study period.

As noted earlier, only a few randomized controlled trials randomized controlled trials (RCTs) have directly explored the impact of statins on renal function. Moreover, the majority of these studies were not placebo controlled and were limited in size or duration and used various statins alone or with other lipid-lowering agents. In a metaanalysis of 12 such studies, Fried et al concluded that statins may retard progression of renal disease and attenuate proteinuria [103]. Similarly, a metaanalysis of data from 27 controlled trials or crossover trials of statins (including close to 40,000 participants) that reported assessment of kidney function showed a significantly slower rate of annual decline in eGFR (1.22 mL/min/year) in the statin-treated participants [104]. The subgroup analysis of the data revealed that the salutary effect of statin therapy was statistically significant in participants with

cardiovascular disease but not in those with glomerulonephritis, diabetic nephropathy, or hypertensive kidney disease. In addition to reducing the rate of decline in GFR, statin therapy modestly reduced proteinuria in this population. The efficacy of statin therapy in lowering proteinuria has been demonstrated in metaanalyses of data derived from 50 trials that included large numbers of CKD and transplant patients reported by Douglas et al. [105] and Strippoli and associates [106]. Unlike the other statins, rosuvastatin lacks antiproteinuric effects and can actually increase proteinuria. This is most likely because concentrations of rosuvastatin and its metabolites is elevated in the renal tissue where it can adversely affect the kidney especially when used in high doses as seen in the "Prospective Evaluation of Proteinuria and Renal Function in diabetic and non-Diabetic Patients with Progressive Renal Disease Trials" (PLANET I and II studies, respectively) trials [107]. These prospective trials were designed to examine the efficacy of a 12-month therapy with rosuvastatin (10 mg or 40 mg/d) and atorvastatin (80 mg/d) on progression of renal disease in diabetic and nondiabetic patients with CKD. The studies revealed reduced proteinuria and slower rate of decline in eGFR in atorvastatin-treated group but modest increase in proteinuria and greater decline in eGFR in rosuvastatin-treated arm, particularly in those receiving the higher (40 mg/d) dose.

Taken together the available data suggest that with the exception of rosuvastatin, statins can be beneficial in retarding progression of CKD especially in those with significant proteinuria. However, these agents should be used with caution as at high doses they can have adverse renal and extrarenal consequences. For instance, Deslypere and colleagues [107] reported that 10 out of 120 patients receiving a high dose of simvastatin (40 mg/d) developed proteinuria that regressed following discontinuation of the drug and reappeared with its reintroduction. The proteinuric effect seen with rosuvastatin and occasionally with other statins appears to be, at least in part, due to impaired proximal tubular reabsorption of filtered proteins. In fact, in vitro studies have shown dose-dependent inhibition of protein uptake by simvastatin, pravastatin, and rosuvastatin in cultured human renal proximal tubular epithelial cells [108].

### ***Mechanisms of protective effects of statins in chronic kidney disease***

The salutary effect of statins on progression of kidney disease is mediated by their cholesterol-lowering and cholesterol-independent actions. In this context, in vitro and in vivo studies have shown that elevated LDL and oxidized LDL can activate mesangial cells, raise matrix production, stimulate release of chemokines and TGF- $\beta$ ,

recruitment of monocytes and their transformation into resident macrophages leading to mesangial matrix expansion, lipid deposition, and foam cell formation [109–112]. These effects are much more intense with the oxidized LDL [77,113] that as noted earlier is significantly increased in patients with CKD.

In addition to their cholesterol-lowering properties, statins can confer renal protection by several cholesterol-independent pleiotropic effects via improvement of endothelial function [114], protection of podocyte [115,116], antioxidant and antiinflammation actions [117,118], reduction of plasminogen activator inhibitor-1 (PAI-1) production [119], suppression of extracellular matrix accumulation [120], and inhibition of VSMCs, mesangial, and monocyte/macrophage proliferation [121–124]. The majority of the cholesterol-independent pleiotropic effects of statins mentioned earlier are due to reduced production of isoprenoids particularly farnesyl pyrophosphate and geranylgeranyl pyrophosphate that are the intermediary metabolites of mevalonic acid. Via isoprenylation or prenylation processes, these intermediary metabolites play a critical part in intracellular transport, membrane anchoring, and regulation of the activities of small guanosine triphosphate (GTP)-binding proteins such as Ras, Rho, Rac, Rap, and Ral [125–130]. These GTP-binding proteins transition between inactive GDP-bound and active GTP-bound forms. As extracellular signal transducers, the GTP-binding proteins regulate many important physiological and pathological functions [131]. The protective effects of statins in kidney disease may be partly due to inhibition of Ras and RhoA [132]. Rac1 that is an important GTP-binding protein plays an essential part in activation of NAD(P)H oxidase. NAD(P)H oxidase is a major source of reactive oxygen species (ROS) in the kidney, vascular tissue, and immune cells. Inhibition of Rac1 signaling by statins has been shown to reduce ROS production in albumin-treated proximal tubular epithelial cells and in high glucose-treated aortic endothelial cells [133,134]. In addition to reducing ROS production, statins have been shown to raise expression of heme oxygenase-1 that catalyzes degradation of heme and generation of the potent antioxidant, bilirubin [135,136]. Moreover, statins have been shown to increase GPX activity [137] and reduce LDL oxidation [138]. Thus by lowering ROS production and raising antioxidant capacity, statins can ameliorate oxidative stress.

Another cholesterol-independent mechanism by which statins may slow progression of CKD is their ability to attenuate inflammation. In fact, statin therapy has been shown to significantly lower serum CRP that is a proinflammatory and prothrombotic mediator. The observed reduction of CRP is partially independent from cholesterol-lowering effects of the drug [139,140]. In addition, statins lower the release of proinflammatory cytokines and chemokines, [141,142], inhibit mesangial

cell and leukocyte proliferation and macrophage infiltration [143], lower expression of profibrotic mediators [144–148], and attenuate expression of leukocyte integrins and endothelial adhesion molecules [149–152]. Besides reducing proinflammatory factors, statins may raise the number of CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells that can help to suppress inflammatory response [153].

In the vascular tissue, statins upregulate expression and activity of endothelial NO synthase [154], suppress the endothelin system [114,155], and attenuate the effects of angiotensin II (Ang II) by lowering AT1-receptor expression [156] and reducing Ang II-stimulated ROS production by inhibiting Rac1 [157]. In addition, by inhibiting PAI-1 production and raising tissue plasminogen activator expression, statins can modify the fibrinolytic balance in the vessel wall [158] and thereby lower the risk of cardiovascular events.

As noted earlier, hypercholesterolemia contributes to CKD progression, in part, by damaging the podocytes [159]. Statins have been shown to attenuate podocyte injury in the model of nephrotic syndrome induced by puromycin aminonucleoside that causes podocyte injury and apoptosis [104]. The protective effect of statins on podocytes appears to be mediated by a p21-dependent antiapoptotic pathway [160]. In fact, statin therapy has been shown to reduce the number of podocytes found in the urine of patients with chronic glomerulonephritis, suggesting diminished podocyte loss and injury by these agents [161].

### **Potential adverse effects of statins**

Besides blocking the synthesis of cholesterol, statins block the production of important intermediary (e.g., farnesyl pyrophosphate and geranylgeranyl pyrophosphates) and alternative (i.e., dolichols and ubiquinone) by-products of mevalonate pathway. Given the important biological functions of these by-products, their diminished production can have adverse consequences. For instance, ubiquinone (coenzyme Q10) is critical for mitochondrial electron transport and oxidative phosphorylation and dolichols are involved in production of glycoproteins that are necessary for tissue growth. In addition, farnesyl pyrophosphate and geranylgeranyl pyrophosphate are necessary for prenylation of proteins, which is essential for intracellular trafficking of newly synthesized proteins between the endoplasmic reticulum and Golgi apparatus, gene transcription, and regulation of cell growth. Therefore by curtailing the availability of these products statins can potentially disturb oxidative phosphorylation, signal transduction, intracellular traffic, gene transcription, and production/regulation of structural proteins [162]. In fact, these unintended effects of statins are responsible for the well-known side effects of statins such as myopathy and liver injury and possibly other less recognized

systemic complications. Theoretically, the antiinflammatory/immunosuppressive properties of statins that are beneficial in attenuating systemic inflammation may raise the incidence and severity of microbial infections that are a common cause of morbidity and mortality in advanced CKD. Interestingly, large randomized clinical trials of statins in the general population have consistently revealed significant reduction in cardiovascular but not the overall mortality [163–165]. These observations indirectly imply that statins may increase mortality from noncardiovascular events probably as a result of the cholesterol-independent effects of these agents particularly when used at high doses.

Taken together statins seem to have salutary effects in CKD and ESKD patients with elevated, but not normal serum cholesterol. Among the available statins, those with minimal renal metabolism/excretion are preferable in CKD patients. Given their various side effects, the lowest effective dose should be used in this population.

### **Peroxisome proliferator–activated receptor- $\alpha$ agonists**

PPAR- $\alpha$  agonists (fibrates) lower serum triglyceride by upregulating LPL and apoA-V and inhibiting apoC-III and increase HDL-chol by raising apoA-1 and apoA-2 expressions. Since hypertriglyceridemia and HDL deficiency are common features of CKD, PPAR- $\alpha$  agonists could be potentially useful in the management of CKD-induced dyslipidemia. A clinical trial of the PPAR- $\alpha$  agonist, gemfibrozil, showed a significant reduction of serum triglyceride, a significant increase in serum HDL-chol and lower incidence of coronary death and nonfatal MI in patients with mild-to-moderate CKD and coronary disease and low HDL-chol level [166]. However, the treatment did not alter the rate of the decline in kidney function. Instead, the drug tended to raise the risk of sustained elevations of serum creatinine in individuals with or without CKD [167,168]. Moreover, the safety and efficacy of these compounds in patients with severe renal disease remains unclear. These concerns have limited the utility of these compounds in the CKD population. Since no dose adjustment is needed for reduced GFR in patients with CKD, the National Kidney Foundation clinical practice guidelines (K/DOQI; 2003) recommended gemfibrozil as the fibrate of choice for the management of dyslipidemias in patients with kidney disease. However, the National Lipid Association has recommended a 50% reduction in the dose of gemfibrozil for patients with GFR below 60 mL/min/1.73 m<sup>2</sup> and avoidance of all fibrates in patients with GFR less than 30 mL/min/1.73 m<sup>2</sup>. Fluvastatin is the only statin, the plasma levels of which are not increased when

combined with gemfibrozil; therefore this combination may be preferred in CKD patients with mixed dyslipidemia [168]. It should be noted that when used concomitantly with statins, fibrates elevate serum level of statins most likely by interfering with the glucuronidation pathway of statin metabolism [168]. The exception is fenofibrate, which does not interfere with statin metabolism. However, major dose reduction is necessary when fenofibrate is used in patients with reduced GFR and the drug should be avoided in patients with GFR below 15 mL/min/1.73 m<sup>2</sup>.

### **Niacin**

At low doses, niacin can raise serum HDL-chol and at high doses it can simultaneously increase serum HDL-chol and reduce serum LDL, triglyceride, and Lp (a) levels. In addition, niacin has antioxidant and anti-inflammatory properties that may further enhance its ability to retard progression of renal disease and atherosclerosis. In fact, animal studies have shown significant attenuation of oxidative stress and lipotoxicity in CKD rats with long-term niacin administration [169,170]. Unfortunately, widespread clinical use of niacin in CKD patients has been limited in part due to its poor tolerability. One of the most common side effects of niacin and related compounds is flushing of the skin that is due to prostaglandin-mediated vasodilation and occurs in more than 80% of patients consuming regular crystalline preparations. The flushing can be attenuated by aspirin taken prior to each dose, use of the drug after meals, or use of the extended-release formulation. The other side effects of niacin include hepatotoxicity, hyperuricemia, and hyperglycemia. Hepatotoxicity that was relatively common with the older generation of sustained-release formulations seems to be uncommon with extended-release niacin. Finally, niacin can raise serum glucose level that may be of concern when prescribed for the diabetic patients. However, the glycemic effect of niacin is dose-dependent and is insignificant at low doses.

### **Cholesterol ester transfer protein inhibitors**

CETP inhibitors markedly raise HDL-chol concentration by inhibiting CETP-mediated exchange of CE for triglycerides in the circulation. The clinical trial of the first product in this class, torcetrapib, was prematurely halted because contrary to expectations the drug increased the adverse cardiovascular outcomes despite marked increase in plasma HDL [171]. Although this phenomenon was attributed to a slight increase in blood pressure observed in the treated group, we believe that despite markedly raising plasma HDL-chol, CETP inhibitors may worsen cardiovascular outcomes in some patients since the increase in HDL-chol in this case is not due to enhanced removal of surplus

cholesterol from the artery wall, kidney, or other tissues. Rather, it is merely due to inhibition of CETP-mediated transfer of CE from HDL to IDL/LDL in exchange for triglycerides in the circulation. In fact, by limiting the conversion of IDL to LDL and formation of CE-rich LDL, inhibition of CETP might lead to accumulation of atherogenic IDL and formation of small dense LDL, events that can accelerate atherosclerosis and intensify inflammation. Subsequently, results of several RCTs evaluating the impact of CETP inhibition on cardiovascular outcomes were similarly disappointing [172–174]. However, as noted earlier, CETP is markedly elevated in patients with nephrotic proteinuria. It is conceivable that low doses of CETP inhibitors may have salutary effect in patients with nephrotic syndrome.

### ***Acyl-CoA cholesterol acyltransferase inhibitors***

These drugs inhibit the intracellular enzyme, ACAT, which is a key factor in cholesterol metabolism. ACAT catalyzes esterification of free cholesterol to CE for incorporation in VLDL in the liver and chylomicrons in the intestine and for sequestration in intracellular vesicles in macrophages, VSMCs, and mesangial cells. The latter is the principal step in foam cell formation and an impediment to reverse cholesterol transport that depends on migration of free cholesterol from cytoplasm to plasma membrane for removal by HDL. Increased ACAT activity augments cholesterol synthesis by the liver and impedes HDL-mediated removal of cholesterol in the peripheral tissues. Consequently, pharmacological inhibition of ACAT can enhance HDL-mediated reverse cholesterol transport, raise plasma HDL-chol and reduce hepatic cholesterol production, events that can have significant protective impact on cardiovascular disease and potentially CKD. However, increased ACAT activity protects the cholesterol-loaded cells against disruption and death caused by high levels of free cholesterol. This is because due to its amphipathic properties, free cholesterol accumulates in the cellular membranes and when present in excess quantities it compromises the stability and physical properties of cell membranes. Therefore by raising intracellular free cholesterol in cholesterol-loaded cells, ACAT inhibitors can cause disruption of plasma membrane in resident macrophages leading to release of proteolytic enzymes and tissue factor, plaque rupture, and thrombosis. In fact, due to adverse cardiovascular outcomes, a large clinical trial of avasimibe that is a potent ACAT inhibitor was halted [175]. It is of note that in a series of studies the authors found a marked increase in ACAT expression and activity in the liver, remnant kidney, and arterial wall in animals with nephrotic syndrome [176] and chronic kidney insufficiency [56]. We subsequently

found significant improvement in proteinuria, renal function, and plasma lipid profile with the administration of ACAT inhibitor, avasimibe, in both conditions [84,176]. It is, therefore, conceivable that low doses of ACAT inhibitors might have potential salutary effects on progression of renal disease in patients with nephrotic proteinuria lacking atherosclerosis.

## Introduction

Regulation of energy balance is dependent on a complex set of mechanisms that are perturbed by chronic kidney disease (CKD), its underlying causes, and the therapies used in its treatment [1]. Patients with CKD face a number of challenges to their nutritional balance that produce adverse changes in nutritional status, including uremia-induced wasting disorders, dialysis-related nutrient losses, and factors such as acidosis, insulin resistance, and chronic inflammation that promote hypermetabolism [2,3]. Very low physical activity in CKD patients is another challenge that also affects energy balance [4]. Nutrition management is, therefore, one of the most important interventions to optimize nutritional status before and after the inauguration of renal replacement therapy, possibly to slow CKD progression, and to prevent and manage uremic toxicity and other complications and comorbid conditions [5,6]. An essential component of effective nutrition management is the determination of energy requirements that considers all the components of energy balance that can be affected by CKD [1], as illustrated in Fig. 5.1. This review presents the current information that integrates previous knowledge with a specific emphasis on energy balance and requirements in CKD. Recommendations related to energy balance in CKD from the recently released 2019 KDOQI (Kidney Disease Outcomes Quality Initiative)/Academy of Nutrition and Dietetics Clinical Practice Guidelines on Nutrition in Kidney Disease [6] are included in this review.

## Energy balance

The human body cannot destroy or produce energy; it takes in energy from food, converts it into usable forms to perform life functions, and then passes it on to the environment [7,8]. The human body loses energy continuously to the environment in the form of heat; to sustain life, this energy must be restored. The source of this energy is the available energy in the highly structured carbon bonds in food, namely, carbohydrate, fat, and protein, which is extracted through oxidation. When a nutrient is oxidized, a part of its energy is thermodynamically obligated for conversion to heat since the heat energy content of the metabolic end products is greater than the available or chemical-free energy content of the initial nutrient. The amount of heat lost is not large, with approximately 95% of ingested energy available as free energy. The conversion of food energy into usable high-energy compounds (such as adenosine triphosphate, ATP) is not very efficient, with more than half of potentially available free energy lost to the environment as heat. This heat loss is essential since it is the basis for the unidirectional nature of metabolic pathways and their regulators. When hydrolysis of ATP is coupled with other reactions, energy retained in ATP can be transferred to other chemical compounds or transformed into mechanical or electrical energy. ATP is the source of energy for muscle contraction, maintenance of ion gradients, electrical conductance, biosynthesis of new molecules, and degradation of organic compounds [9].

The concept of energy balance is based on the first law of thermodynamics: energy is conserved [10].

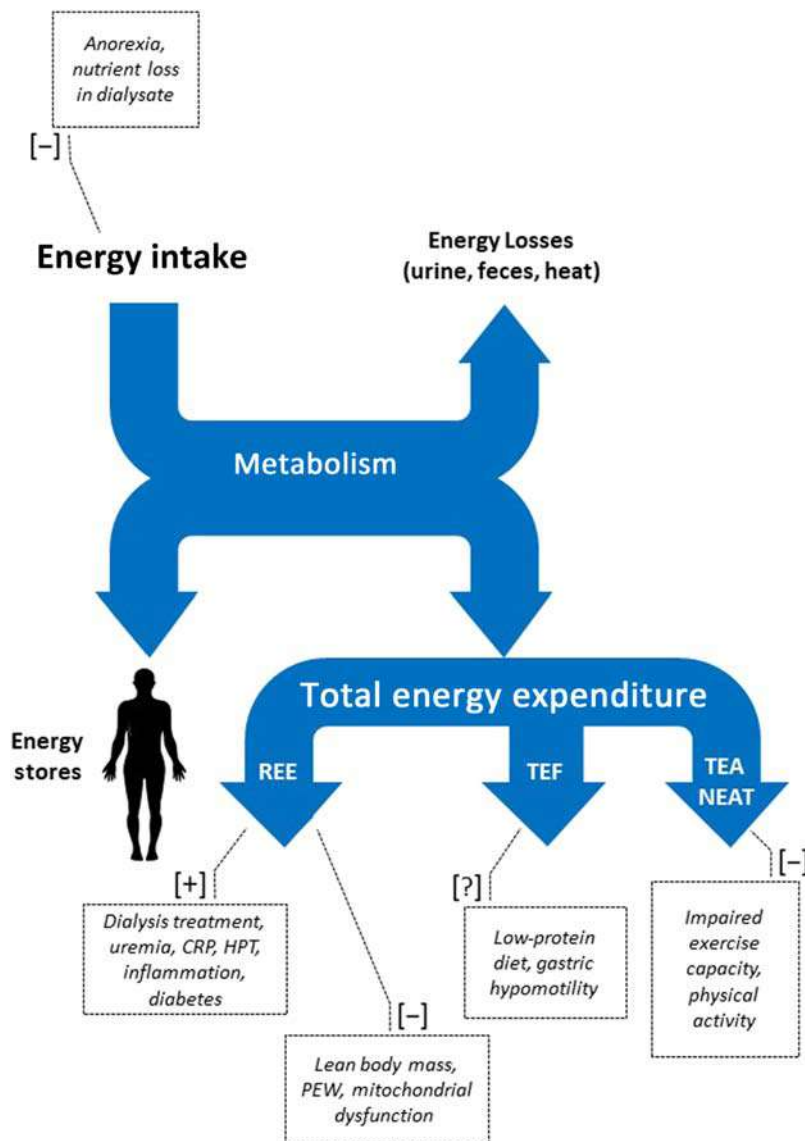

FIGURE 5.1 Principles of energy balance and components affected by CKD. CKD, Chronic kidney disease.

Energy balance is the difference between energy intake and energy output. Energy intake consists of the metabolizable energy of the foods consumed, and energy output represents the total energy expended [11]. Conservation of energy implies that the chemical energy stored in food is converted into work, thermal energy, and/or stored as chemical energy in fatty tissue. If energy intake is greater than energy output, a person is in positive balance and is storing energy as fat, carbohydrate, and protein. If energy output is greater than energy intake, a person is in negative balance and must be oxidizing endogenous stores of energy [9].

When humans ingest carbohydrates, proteins, or fats, they either oxidize them immediately and use the energy released to do work or transform them into forms that can be stored as potential energy [9]. The body stores energy as fat, glycogen, and protein.

Differences in the metabolizable energy of dietary fat and carbohydrate mean that an increase in the quantity of fat in the diet is more critical than a comparable increase in carbohydrate when determining whether stores of triglycerides in adipose tissue will be increased [12].

When exogenous energy is not available, as occurs during an overnight fast, the body derives energy from its endogenous fuels [9]. Most of the energy stored in the body is as fat. A normal 70-kg man has about 13 kg of fat, which can yield approximately 125,000 kcal (525,000 kJ) on oxidation. Body protein is also lost during a total fast [7,13]. A normal man has about 11 kg of protein of which 7 kg are intracellular and 4 kg extracellular. The extracellular or structural proteins in bone and connective tissue are very stable and are considered to largely be unavailable for

metabolic needs. The intracellular proteins, which make up much of the body's active cell mass, serve many functions but are chiefly enzymes and contractile proteins; there are no storage proteins. Due to the essential functions of protein, loss of large amounts of body protein may lead to adverse functional consequences that are conventionally considered to be the cause of death in long-term starvation [14,15]. Finally, the body contains between 1000 and 3000 kcal of carbohydrates stored in the liver and muscles as glycogen. This energy source is available for immediate energy needs, such as exercise, but is of little value during long-term fasting by virtue of its limited supply.

Suboptimal nutritional status in the form of protein-energy wasting (PEW) and overweight/obesity are the most frequent nutritional imbalances observed in CKD. PEW is defined as abnormally low levels or excessive losses of body protein mass and energy reserves [16]. Worldwide, the prevalence of PEW in CKD (stages 3–5) ranges from 18% to 80% [16–18]. Overweight/obesity and diabetes mellitus are some of the leading causes of CKD [19]. Around 20%–60% of CKD patients (stages 3–5) have a body mass index (BMI) greater than 25 kg/m<sup>2</sup> and almost half of the individuals with CKD also have diabetes and self-reported cardiovascular disease [20]. The causes of PEW and overweight/obesity in CKD are multifactorial and center around the common theme of energy imbalance [21]. As shown in Fig. 5.1, all the components of the energy balance equation have the potential to be altered because of CKD.

## Energy intake

The fundamental basis for measuring energy intake is that in weight-stable individuals, energy intake is equal to total energy expenditure (TEE) [22–26]. Both prospective and retrospective methods have been used to assess dietary intake at the individual level, including food records, 24-hour recalls, and food-frequency questionnaires (FFQs). The gold standard for assessing the validity of dietary intake instruments is to compare the reported intake to the doubly labeled water (DLW) measures of energy expenditure [22]. The food record is an example of a prospective, quantitative method in which the participant records all foods and beverages and the amount of each consumed on a daily basis. The food record is usually collected over a 3- to 14-day period [22,23]. The strength of the food record method is its ability to capture quantitative information because all foods and beverages are weighed or measured before consumption. However, food records are subject to systematic errors such as underreporting, especially

by certain populations (such as obese individuals or chronic dialysis patients) and their potential to influence and alter eating habits during data collection, which reduces the accuracy of usual intake estimates [24].

Retrospective dietary assessment instruments rely on the memory of the participant to recall foods or beverages consumed in the past; they include the 24-hour recall, diet history, and FFQ [22,23]. A 24-hour recall requires the respondent to recall in detail the foods and beverages consumed during the previous 24 hours. Data can be collected over a single 24-hour period or averaged from multiple 24-hour recalls conducted on both weekdays and weekend days. Although this method is quick and inexpensive, it has major limitations of rarely representing an individual's typical intake, it relies on memory, and often foods are omitted leading to low estimates of energy intake [23]. Finally, the FFQ requires that respondents report the frequency of consumption of foods from a list of foods over a specific time period. A strength of the FFQ is its easy and simple administration and ability to capture the intake of infrequently consumed foods [22,25]. However, FFQs are thought to have low precision at the individual level, are only semiquantitative, and are subject to misreporting errors [24].

In CKD, it is critical to accurately measure energy intake as part of an overall assessment of clinical and nutritional status, especially in the absence of the ability to directly measure TEE. Reduced energy and/or protein intake, associated with loss of appetite, has been associated with a decline in nutritional status, characterized by changes in serum albumin and increased risk of morbidity and mortality in patients with advanced CKD [2,3]. In fact, the prevalence of appetite loss among advanced CKD patients is reported to be 35%–50% [27,28]. As kidney function declines, food intake decreases, and this decrease correlates with the accumulation of nitrogen-derived uremic toxins [16,29]. In stable appearing maintenance hemodialysis (MHD) patients, fair or poor appetite can be associated with serological evidence for inflammation and increased mortality [30]. Abnormalities of the digestive system are additional factors beyond metabolic disturbances that may affect food intake [2]. Certainly, for CKD patients, inadequate dietary intake has been identified as the most frequent cause of PEW [27]. PEW is a manifestation of a progressive anorexia, which results from increases in anorexigenic hormones [31] and activation of proinflammatory cytokines, all of which lead to inadequate dietary protein and energy intakes. In a cross-sectional study, Kopple et al. [29] reported that in CKD patients, dietary protein and energy intakes, as well as serum and anthropometric measures of protein-energy status, progressively declined as estimated glomerular filtration rates (GFRs) decreased. In fact, the probability of PEW is inversely related to estimated GFRs [32]. As a

result, PEW is more common in the more advanced stages of CKD.

Among clinically stable CKD patients, a contradiction exists between the observation of a stable body mass despite reported insufficient energy intakes [33–35]. This discrepancy may be due to underreporting of energy intake due to the poor accuracy of dietary assessment tools; this underreporting may affect the interpretation of health and diet studies [26] which can potentially lead to erroneous energy recommendations. Published data demonstrate an underreporting of dietary energy intake in nondialyzed advanced CKD patients [36,37], as well as in those undergoing MHD [33,34,38,39] and peritoneal dialysis (PD) [18]. The prevalence of underreporting is significant and has been observed in 72.5% of nondialyzed CKD patients [36,37], 52.5% of PD patients [18], and 77%–92% of MHD patients [33]. It is interesting to note that underreporters tend to have a high BMI when compared to valid reporters [18,36,37], an association that is routinely seen in individuals without CKD. Nevertheless, with proper training and extended recording periods (7 days), food records can provide accurate information about energy intake in CKD [40,41]. Furthermore, the reliability of these various tools and therefore the correct interpretation of data extracted from them is facilitated by integrating the dietary intake data into an overall picture of the patient's nutritional status, including weight change, level of physical activity, metabolic stressors, and treatment goals.

The 2019 Clinical Practice Guidelines on Nutrition in CKD [6] considers dietary intake data essential for the nutritional management of CKD patients and recommends the use of a 3-day food record, which includes both dialysis and nondialysis treatment days, as the preferred method to assess dietary intake in adults with CKD stages 3–5D. Twenty-four-hour food recalls and FFQs are considered alternative methods to assess dietary energy intake. The guidelines also recommend that to effectively plan nutrition interventions, factors beyond dietary intake must be taken into consideration (i.e., the patient's medication, knowledge, beliefs, attitudes, behavior, access to food, depression, and cognitive function).

## Energy expenditure

An individual's energy requirements are the energy intakes that will balance TEE. Energy is expended by the body in the form of basal energy expenditure (BEE), resting energy expenditure (REE), the thermic effect of food (TEF), and physical activity thermogenesis or the work derived from all forms of physical

activity, postural maintenance, and muscular contraction [exercise [thermic effect of activity (TEA)] and nonexercise activity [nonexercise activity thermogenesis (NEAT)]] [9,42]. These components make up a person's total daily energy expenditure. Regulation of energy balance is based on a complex set of feedback mechanisms that involve the endocrine system, central nervous system, and body energy stores and are aimed at restoring balance and maintaining body weight or, more precisely, body energy stores [1,12]. The main determinants of energy balance and the regulatory mechanisms of energy homeostasis in CKD are affected by both the underlying disease processes and the treatments for the disease (i.e., renal replacement therapy) [1,28]. In addition to the standard determinants of energy expenditure (age, sex, and fat-free mass, FFM), patients with CKD on MHD or PD often experience hyperparathyroidism (HPT), hyperglycemia, and chronic inflammation, which must be considered when assessing energy needs. As with any individual, illness, injury, and nutritional status goals (weight maintenance, loss, or repletion) are also factors that determine energy needs. Finally, the stage of CKD and the mode of renal replacement therapy are factors that have the potential to influence energy intake, energy expenditure, and, therefore, overall energy needs.

### **Basal energy expenditure and resting energy expenditure**

BEE is the minimum amount of energy expended that is compatible with life. BEE typically represents 60%–70% of TEE. The REE is the amount of energy expended by a resting individual in a thermoneutral environment without the effects of meal consumption, physical activity, or physiological or mental stress [9,13,43,44]. REE may be 10%–20% greater than the true basal metabolic rate. REE also differs from BEE; in that, it is measured in the morning upon awakening after 12–18 hours of rest and is dependent on the circadian rhythms at that time of day [13,43,45,46]. The energy expended at rest includes the costs of maintaining the biochemical and structural integrity of the body; performing internal work, ion pumps, synthesis, and degradation of cell constituents; biochemical cycles; and leakage of protons across the mitochondrial membrane [9]. The effects of CKD on REE are described in the “Energy balance and chronic kidney disease” section.

### **Thermic effect of food**

The TEF is manifested as the increase in energy expenditure immediately following meal ingestion [45,47]. It is also referred to as diet-induced thermogenesis and the specific dynamic action. The primary

determinants of TEF are the nutrient composition and energy content of the food consumed [45,48]. All TEF studies agree that protein induces the greatest increase in the metabolic rate [48,49], followed by a mixed nutrient meal, carbohydrates, and then fat [49,50]. The second determinant of the magnitude of the TEF is the energy content of the meal. It is well established that the magnitude of the TEF is closely correlated to the energy load provided in a test meal [51].

The effects of CKD on TEF do not appear to have been evaluated. However, several factors common to CKD may affect the contribution that TEF has to TEE. First, gastrointestinal symptoms are common in patients with CKD and can be related to gastric hypomotility [52]. One way in which the TEF might be affected is due to the load of the meal being spread out over a greater time frame. Furthermore, uremia, as well as dietary restrictions and pharmacotherapy, may alter the gut microbiome [52]. Alterations in the gut microbiome have been implicated in energy regulation, although not specifically related to TEF. Finally, patients with advanced CKD often consume a low-protein diet. Since protein has the highest TEF, a low-protein diet would likely decrease the TEF portion of TEE. To the authors' knowledge, the effect that these factors may have on TEF and energy balance has not been examined in CKD patients or experimental models of CKD.

### ***Thermic effect of activity***

Physical activity is defined as any bodily movement produced by skeletal muscles, which results in energy expenditure. The TEA is the energy expended above the resting level, both during and after physical activity. Activity thermogenesis can be conceptually divided into purposeful or intentional activity (exercise) and NEAT. For sedentary individuals, purposeful sporting exercise is minimal and so their exercise-related activity thermogenesis is zero; for those who do exercise regularly, exercise-related energy expenditure is generally 15%–30% of the total daily energy expenditure [12,43,44,53]. The contribution of exercise to TEE depends on the intensity of the work performed and the duration of the sum of all activities over the day. The variability of this component means that the rate of energy expenditure can be as low as 1.5 times the REE for clerical work or as high as 15 times the REE for running.

NEAT or the energy expenditure of spontaneous physical activity includes the combined energy costs of the physical activities of daily living, fidgeting, spontaneous muscle contraction, and maintaining posture when not recumbent and accounts for the remainder of the total daily energy expenditure for most individuals [42]. Occupation and leisure time are the two

major predictors of NEAT and can range from 15% to more than 50% of an individual's total daily energy expenditure [42].

In CKD patients, nutrition and physical activity are closely associated [54]. Inadequate energy intake impairs physical performance, which favors a sedentary lifestyle and contributes to loss of muscle strength and mass [54]. In fact, it is well documented that physical activity is diminished in CKD especially in those undergoing dialysis treatment, although the contribution of low dietary energy intake to reduced daily physical activity of chronic dialysis patients has not been examined [55–57]. Impaired exercise capacity has even been described in nondialyzed CKD patients [58] who are reported to have lower median peak oxygen consumption levels, which can limit exercise capacity to the extent that activities of daily living are impaired [56]. Increased risk for mortality, possibly related in part to the increase in inflammatory markers that occur in association with loss of muscle mass [54–58], has also been associated with physical impairment in CKD (stages 2–4) [59]. Mafra et al. [35] reported that inflammation had a negative effect on TEA, a positive effect on REE, with an overall negative net effect on TEE. They concluded that patients with inflammation were less active and, consequently, their TEE was lower as compared with patients without inflammation. This decrease in activity-related thermogenesis may be a component of adaptation to the disturbances in energy homeostasis frequently observed in CKD. The contribution of exercise and physical activity to TEE is not fully understood and is identified as a future research priority in the 2019 Clinical Practice Guideline on Nutrition in CKD [6].

### ***Factors that influence energy expenditure***

Since 1915, when Benedict suggested that the “active body mass” determines the REE, it has been recognized that the amount of FFM in the body (body mass minus total fat mass) is highly predictive of the REE [7,43,60,61]. About 50%–80% of the variance between people in their REE can be accounted for by their FFM [7,43]. Even though REE and FFM are strongly correlated, the correlation is not linear in normal weight individuals, probably because of the varying compositions of the FFM at different total FFMs [43,60,61]. Anatomically as well as metabolically, FFM is heterogeneous. It consists of organs with a high metabolic rate and it also comprises skeletal muscle and bone mass with relatively low metabolic rates. Elia [62,63] highlighted the existence of large between-organ differences in the specific resting metabolic rate ( $K_i$ ; metabolic rate for individual organs and tissues under resting conditions) values for seven organs and tissues in young adults with normal body weight,

including 200 for liver, 240 for brain, 440 for heart and kidneys, 13 for skeletal muscle, 4.5 for adipose tissue, and 12 for residual mass (all units are in kcal/kg/day). Residual mass includes skeleton, blood, skin, gastrointestinal tract, lung, spleen, and other organs and tissues present in small amounts. According to Wang et al. [64], under resting conditions, heart and kidneys have the highest metabolic rates, twice those for liver and brain, as seen in Fig. 5.2. After the heart, the kidney has the second highest mitochondrial content and oxygen consumption [65]. The high resting metabolic rate for the kidney is related to the requirement for a high mitochondrial content to provide sufficient energy for tasks that are driven by ion gradients generated from  $\text{Na}^+\text{-K}^+\text{-ATPase}$ , such as nutrient reabsorption, blood pressure regulation, and maintenance of acid–base homeostasis [66]. However, the

mechanism by which mitochondrial dysfunction contributes to energy balance in CKD is unclear.

Thyroid hormones (THs) play an important role in the regulation of energy expenditure. However, it is not known which of the triiodothyronine (T3) sensitive processes are most physiologically relevant for energy expenditure [67]. Numerous studies performed over the past century have demonstrated that TH helps to regulate energy expenditure in man. Administration of T3 to obese patients increases oxygen consumption even when these patients ingest an energy-restricted diet [68]. Thyroidectomy is followed by a significant (40%) decrease in BEE [69]. In a study of patients requiring chronic TH replacement, there was a significant negative correlation between REE and thyroid-stimulating hormone (TSH) [70]. THs are also important components of the metabolic adaptations associated with energy restriction and overfeeding [68]. THs directly and indirectly modulate the behavior of many metabolic pathways potentially relevant for energy expenditure. The direct effects refer to TH actions that increase ATP utilization related to metabolic cycles and ion leaks, while the indirect effects increase the capacity for energy expenditure through nongenomic pathways and mitochondrial biogenesis, as well as a decrease in metabolic efficiency at the stage of ATP production, by activating uncoupling mechanisms [67–70].

With respect to the kidney, TH directly influences renal growth and development, GFR, renal transport systems, and sodium and water homeostasis [71]. The thyroid–kidney mechanistic link has not been fully described but is thought to be bidirectional [72]. Studies have consistently shown that hypothyroidism and subclinical hypothyroidism are highly prevalent in the CKD population [73–75]. In addition, various thyroid functional test abnormalities are frequently seen in CKD patients, resulting from alterations in TH synthesis, metabolism, and regulation [73]. CKD is also known to be the cause of nonthyroidal illness [76], characterized by low T3 syndrome in the absence of underlying intrinsic thyroid disorder. With respect to renal replacement therapy, lower T3 and T4 values, higher TSH levels, higher frequency of low T3 syndrome, and subclinical hypothyroidism are more frequently observed in MHD patients as compared with healthy subjects [77]. Similarly, primary hypothyroidism, especially subclinical hypothyroidism, is not uncommonly encountered in PD patients [78,79]. Finally, studies have reported that the most common thyroid imbalance in renal transplant recipients is a low T3 syndrome with free T3 levels in the normal range [80,81]. The role that these disturbances in thyroid function have on energy metabolism in CKD patients has not been specifically evaluated. However, it has been suggested that low serum-free T3 levels in

FIGURE 5.2 Proportional contribution of organs and tissues to calculated REE. REE, Resting energy expenditure.

uremia may be the result of an appropriate adaptive process aimed at reducing energy expenditure and minimizing protein catabolism [82,83].

## Measurement of energy expenditure

The variability of measured energy intake between individuals is greater than that of energy expenditure. Theoretically, energy requirements can be estimated by monitoring chronic dietary intake in people who are not gaining or losing weight. However, this is deceptively difficult to do because when dietary energy intake is measured, food and energy intake often change [11]. This suggests that energy requirements can be estimated more accurately from energy expenditure than from energy intake measurements [11]. Energy expenditure can be assessed by two different techniques: those that are calorimetric in nature (direct and indirect calorimetry) and that are noncalorimetric (DLW and energy intake) [11,43,44,84].

### Direct calorimetry

The direct method for measuring metabolic rate involves the measurement of heat losses. Direct calorimetry measures the sum of radiant heat exchange and of convective, conductive, and evaporative heat transfer [43,44]. The total heat loss is equal to the rate of energy utilization when body temperature is constant [10,85,86].

Direct calorimetry has the advantage of being based solely on the direct measurement of heat generation and not on any assumptions about the physiology of energy metabolism, but it requires expensive instrumentation. The subject is placed in a thermally isolated chamber and the heat he/she dissipates is collected and measured [85]. This method is limited by the confining nature of the testing environment. Furthermore, direct calorimetry cannot be used to measure the short-term effects of thermogenic stimuli, such as food, on heat exchange due to the large heat storage capacity of the body [7,85]. It is also very costly. As a result, direct calorimetry is infrequently used.

### Indirect calorimetry

Indirect calorimetry is the method by which metabolic rate is estimated from measurements of oxygen consumption and carbon dioxide production and is based on a series of assumptions and equations [43,85–88]. Indirect calorimeters can measure energy expenditure in both mechanically ventilated and spontaneously breathing patients. The measurement is based on the assumption that all the  $O_2$  consumed ( $VO_2$ ) is used to oxidize degradable fuels and all the  $CO_2$  produced in the body ( $VCO_2$ ) is recovered [9].

Calculating energy production in this situation is equivalent to converting the chemical-free energy of nutrients into the chemical energy of ATP plus loss of some energy (as heat) during the oxidation process, plus the ultimate conversion of the chemical energy to heat lost to the environment (plus any external work performed on the environment). Eventually, all energy is converted into heat so direct and indirect calorimetry should and do provide identical rates of energy expenditure under steady-state conditions [86]. The accuracy of respiratory gas exchange as an indicator of energy expenditure has been reported to be accurate to within 2% [10].

The 2019 Clinical Practice Guidelines on Nutrition in CKD [6] recommends that indirect calorimetry to measure REE is used to assess energy requirements when feasible and indicated in adults with CKD stages 1–5D and posttransplant. This recommendation represents a shift to a more personalized, patient-centered approach; however, the practicality of measuring rather than estimating REE makes it unlikely to be widely applied in the clinical setting at this time.

### Doubly labeled water

The DLW method is based on the observation that the oxygen in respiratory carbon dioxide is in isotopic exchange equilibrium with the oxygen in body water [44]. The basis of DLW is that two isotopes of water ( $H_2^{18}O$  and  $^2H_2O$ ) are given and their disappearance rates from the body (from body fluid such as urine) are monitored for a period of time optimally equivalent to 1–3 half-lives for isotope disappearance (7–21 days in most human subjects) [89]. The disappearance rate of  $^2H_2O$  reflects water flux, while that of  $H_2^{18}O$  reflects water flux plus carbon dioxide production rate. The difference between the two disappearance rates can be used to quantify the carbon dioxide production rate. To predict TEE from a measurement of carbon dioxide production, the respiratory quotient of the subject during the measurement period must be estimated [90]. The DLW method has been validated by comparing DLW-derived estimates of TEE with measurements made in a whole-body calorimeter [89,91]. While this technique for assessing energy expenditure appears highly reliable, it is not considered practical for outpatient clinical use. It also has limited use in CKD due to dialysis-induced shifts in body water, which can alter the isotopic abundance of the body.

## Energy balance and chronic kidney disease

As illustrated in Fig. 5.1, CKD has the potential to affect many aspects of energy balance. The overall impact of CKD on energy balance can be both positive,

with body weight (adipose tissue) gains, and negative, with fat loss. Many clinical disturbances and the treatments [92–94] associated with CKD have the potential to increase catabolism and elevate REE. Conversely, low energy intake can produce metabolic changes similar to those seen with adaptation to starvation, namely, reduced REE, body fat loss, and reduced physical activity [15]. Ku and coworkers [95,96] found that in both adults and children with CKD, weight/BMI declines significantly after eGFR falls below about 35 mL/min/1.73 m<sup>2</sup>. Furthermore, they found a 55%–60% higher adjusted rate of death after starting either hemodialysis or PD in patients with a predialysis annualized weight loss greater than 5%. Although not measured, this weight loss presumably reflects decreased food and energy intake. The 2019 Clinical Practice Guidelines on Nutrition in CKD [6] underscores the importance of patterns of weight change since they can provide insights into the appropriate timing of nutritional interventions that might achieve the greatest impact on outcomes of patients with CKD [95,97,98]. The guidelines recommends monitoring body weight/BMI and body composition for changes at least monthly in MHD and PD patients, every 3 months in stages 4–5 and posttransplant patients and every 6 months in stages 1–3 patients [6].

One of the most common disturbances to energy balance today is the development of overweight/obesity. Obesity increases the risk for type 2 diabetes, cancer, hypertension, dyslipidemia, cardiovascular disease, sleep apnea, CKD, and chronic kidney failure [99]. The prevalence of obesity in patients with kidney failure is increasing faster than the prevalence of obesity in the general population [100], which suggests that obesity is a risk factor for CKD and its progression to kidney failure [101]. The prevalence of obesity among US patients awaiting a kidney transplant had also increased [100] and obesity has been identified as an independent risk factor for complications occurring during or after kidney transplant surgery including graft loss and patient death [102,103]. Weight management in CKD patients remains a controversial topic. On the one hand, weight loss in the predialysis phase may slow the progression of kidney disease [104]. On the other, obesity has been shown to confer a survival advantage in obese patients on dialysis and may reduce short-term mortality associated with malnutrition, inflammation, and PEW [5,104]. As a result of this obesity paradox, the appropriate weight management approach of overweight/obese predialysis and dialysis patients has not yet been established [101].

In general, studies report normal energy requirements in clinically stable CKD patients [92,94,105–111]. Most of the published data showed that REE of clinically stable chronic dialysis patients is normal in dialysis-dependent patients and below normal in nondialyzed

CKD patients in comparison to the REE of healthy controls. Monteon et al. [39] were the first to examine the REE of nondialyzed CKD patients and MHD patients and showed that REE was not different from that of healthy controls. Similar findings have been reported in patients on both hemodialysis and PD [106,112]. In nondialyzed CKD patients, REE was reported to be about 100–200 kcal/day lower than that of healthy individuals in some studies [17,113] but not all [39]. Conversely, a study by Ikizler et al. [92] reported a significant 15%–20% increase in energy expenditure in MHD patients during dialysis sessions compared with control subjects. Although this data was characterized as REE, the patients had, in fact, eaten prior to the assessment of energy expenditure suggesting that some of this increase can be attributed to the TEF. The same patients had their REE measured on the interdialytic day after a 12-hour fast and were found to have a 7.5% increase in REE compared with control subjects. Finally, Shah and coworkers [114,115] concluded that the average daily energy requirements of MHD patients were similar to those of sedentary normal individuals, although there was wide variability among individual patients.

REE has been examined within PD cohorts with a wide array of comorbidities and varying degrees of residual renal function. Loss of residual renal function in PD patients has been shown to be associated with increased REE [116,117]. In fact, although several factors [diabetes, cardiovascular disease, C-reactive protein (CRP)] are positively associated with REE, residual renal function showed the strongest inverse relationship in this patient population. These data suggest that diseased kidneys likely remain a metabolically highly active organ and contribute to the REE of PD patients. It should be noted that increased uremia, inflammation, and secondary HPT also occur with the decline in renal function and may relate to the increased REE [118–121]. Stenvinkel et al. [121] showed that increased leptin levels in PD patients are associated with inflammation and loss of lean body mass. In the hypothalamus, leptin plays an important role in the regulation of energy homeostasis. In PD patients, it has been suggested that the net result of increased leptin is reduced intake and increased energy expenditure, which are known features of PEW [122].

The lack of consistent findings across the spectrum of CKD may be related to large variations in the degree of clinical disturbances that afflict CKD patients. This may be the reason that the reported energy requirements in stable CKD patients vary considerably [123]. It is likely that unless a chronic or severe condition is present, these disturbances will only have a modest effect on energy expenditure [1]. On the other hand, it has been clearly demonstrated that REE is increased with catabolic conditions often

observed in patients with CKD, such as poorly controlled diabetes mellitus, severe HPT, and inflammation. Avesani et al. [109] showed that the REE in nondialysis CKD patients with poorly controlled diabetes was 12.5% greater than that of nondiabetic nondialyzed patients with CKD. Patients with severe HPT had significantly higher REE than patients with moderate HPT or healthy controls and 6 months after parathyroidectomy, the REE decreased significantly [108]. While the great majority of CKD stages 1, 2, and 3A patients do not have increased inflammatory markers, in some studies, 30%–50% of nondialyzed advanced CKD patients [111] and dialysis [124] patients present serologic evidence of an activated inflammatory response with elevated serum CRP. Avesani et al. [109] reported increased REE in nondialysis patients with CRP greater than 40.5 mg/dL. Finally, Utaka et al. [94] showed that after treatment of infection/inflammation, a significant decrease in CRP was accompanied by a 13% reduction of REE. Individualized, patient-centered assessment of energy requirements is clearly critical to effectively provide nutrition therapy in CKD.

The transition from kidney failure to kidney transplant is a metabolic challenge due to hormonal shifts, variations in energy expenditure, and the metabolic disturbances associated with immunosuppression therapies [125]. The hypercatabolic state that may be present with

advanced CKD typically recovers in the first year after transplant [126]. In the early stages of postkidney transplant, surgical stress and increased doses of immunosuppressive drugs can lead to net protein catabolism and increased energy expenditure [127,128]. After successful transplantation with recovery of renal function, there is an improvement of nutritional status and oxidative stress, as well as a decrease in REE [128]. Ultimately, REE measured in transplanted patients [129] are similar to those estimated in healthy controls [130].

## Predictive energy equations

In CKD, the preferred method to determine energy requirements is to measure REE using indirect calorimetry [131]. However, this approach is infrequently used in the clinical setting, because the method is both cumbersome and costly [132,133]. Table 5.1 lists the most commonly used predictive equations and recently developed disease-specific equations to estimate REE. The equations proposed by Mifflin and St Jeor in 1990 [109], Schofield in 1985 [134], and Harris and Benedict in 1919 [135] provide validated estimations of REE as compared with indirect calorimetry and are used routinely in healthy individuals [136]. Traditionally, these equations incorporate variables such as gender, age, height, and weight as predictors of measured REE. There has been limited

TABLE 5.1 Predictive energy equations.

<b>Harris–Benedict RMR<sup>a</sup> [135]</b>		
Men	$66.47 + 13.75 \times \text{weight} + 5.0 \times \text{height} - 6.75 \times \text{age}$

<sup>a</sup>Healthy patients, weight in kilograms (kg) and height in centimeters (cm).

<sup>b</sup>Healthy patients, reported by the World Health Organization, height in meters (m).

<sup>c</sup>Dialysis patients, height (cm), weight (kg), age (years).  $\text{Factor}_{\text{age}}$  is 0 if age is <65 years or 1 if >65 years.  $\text{Factor}_{\text{sex}}$  = 0 if female or 1 if male.

<sup>d</sup>MHD patients, age (years), postdialysis weight (kg), and CRP (mg/dL).

CRP, C-reactive protein; MHD, maintenance hemodialysis; REE, resting energy expenditure; RMR, resting metabolic rate.

success in extrapolating these predictive equations to CKD [35,137]. The Harris–Benedict equation has been shown to both overestimate REE across the different stages of CKD [138–141] and to underestimate REE in MHD [142]. The Schofield equation also is reported to both overestimate REE in nondialyzed, MHD and PD patients [138,139,142] and to underestimate REE in MHD patients [136]. Finally, the Mifflin–St Jeor equation is reported to underestimate REE in MHD patients [114].

More recently, CKD-specific equations that incorporate both demographic and clinical variables as predictors of REE have been proposed [142,143]. Byham-Gray et al. [143] incorporated CRP as a variable in their equation and had greater precision in estimating REE as compared to the Mifflin–St Jeor equation [115]. Vilar et al. [142] developed a dialysis-specific equation (MHD and PD) which used standard demographic variables as predictors of REE; they also concluded that their equation was better than traditional predictive equations for REE in MHD or PD patients. Consistent with these findings, the 2019 Clinical Practice Guidelines on Nutrition in CKD [6,144] recommends that if indirect calorimetry is not available, disease-specific predictive equations may be used to estimate REE in metabolically stable adults with CKD 5D on MHD. But this remains a needed area for further study as these equations have not been validated in large populations to the same extent as those developed for healthy populations.

### Overview and recommended energy intake in chronic kidney disease patients

The World Health Organization defines energy requirements as “the amount of food energy needed to balance energy expenditure in order to maintain body size, body composition and a level of necessary and desirable physical activity consistent with long-term

good health” [134]. They caution that dietary energy needs must be considered within the context of other nutrients in the diet since the lack of one will influence the others. There are several reasons why this is a consideration of critical importance in CKD: adequate energy intake is needed for effective utilization of dietary protein; protein-energy malnutrition is a common cause of PEW [118,145]; reduced dietary energy intake is common [146]; nondialyzed advanced CKD patients are often prescribed low-protein diets that may increase their risk of protein wasting when energy intake is marginal or insufficient; and PEW is associated with increased morbidity and mortality in these individuals [32,147].

Table 5.2 summarizes recommended energy intakes across the CKD spectrum. A consistent recommendation of 25–35 kcal/kg/day is based on the amount needed to maintain body protein stores and nitrogen balance and includes patients consuming the full range of dietary protein intakes. The recommendations are calculated based on desirable body weight rather than actual body weight. Ideal body weight (IBW) is typically used as a surrogate for desirable body weight because it is the weight associated with the lowest mortality in the general population for a given height, age, sex, and frame size based on the Metropolitan Life Insurance Height and Weight Tables.

In 2010 the Academy of Nutrition and Dietetics (Academy) and the National Kidney Foundation’s KDOQI [148] put forth guidelines for patients with CKD and end-stage renal disease. In 2019 KDOQI, in collaboration with the Academy, updated its Clinical Practice Guideline on Nutrition in CKD [6]. These recommendations are consistent with previous guidelines and reflect the current literature:

Methods to assess energy requirements:

- Adults with CKD 1–5D and posttransplant: use indirect calorimetry to measure REE when feasible and indicated.

TABLE 5.2 Recommended energy intake in adults, according to chronic kidney disease (CKD) stage.

CKD stage	Energy (kcal/kg/day)
Increased CKD risk with normal kidney function <sup>a</sup>	30–35; adjust for weight reduction (IBW) if BMI >30
Mild, moderate, advanced CKD <sup>b</sup>	30–35; increase proportion of LPD
Transition to dialysis	30–35
Dialysis dependent or any stage with PEW (existing or imminent)	30–35; higher intake if PEW present or imminent
Kidney transplant <sup>a</sup>	30–35
CKD and overweight/obese <sup>a,c</sup>	<30

<sup>a</sup>In obese patients, lower energy ranges used based on IBW for weight reduction [5,6].

<sup>b</sup>LPD for management of CKD [5].

<sup>c</sup>In overweight/obese patients, diet to significantly reduce BMI [6].

BMI, Body mass index; CKD, chronic kidney disease; IBW, ideal body weight; LPD, low-protein diet; PEW, protein-energy wasting.

- Adults with CKD 5D on MHD who are metabolically stable, in the absence of indirect calorimetry, disease-specific predictive energy equations may be used to estimate REE as they include factors that may influence the metabolic rate in this population.

Methods to assess protein and calorie intake:

- Adults with CKD 3–5D, use a 3-day food record, conducted during both dialysis and nondialysis treatment days (when applicable), as a preferred method to assess dietary intake.
- Adults with CKD 3–5 nondialyzed and 5D: 24-hour food recalls, FFQs, and normalized protein catabolic rate/normalized protein nitrogen appearance may be considered as alternative methods of assessing dietary energy and protein intake.

Recommended energy intake:

- Adults with CKD 1–5D and posttransplant who are metabolically stable: prescribe an energy intake of 25–35 kcal/kg IBW per day based on age, gender, level of physical activity, body composition, weight status goals, CKD stage, and concurrent illness or presence of inflammation to maintain normal nutritional status.

## Abbreviations

ATP	adenosine triphosphate
BEE	basal energy expenditure
BMI	body mass index
CKD	chronic kidney disease
CRP	C-reactive protein
FFM	fat-free mass
FFQ	food-frequency questionnaire
HPT	hyperparathyroidism
IBW	ideal body weight
KDOQI	Kidney Disease Outcomes Quality Initiative
MHD	maintenance hemodialysis
NEAT	nonexercise activity thermogenesis
PD	peritoneal dialysis
PEW	protein-energy wasting
REE	resting energy expenditure
TEA	thermic effect of activity
TEE	total energy expenditure
TEF	thermic effect of food
TH	thyroid hormone

# Uremic toxins: an integrated overview of classification and pathobiology

Richard J. Glasscock<sup>1</sup> and Shaul G. Massry<sup>2</sup>

<sup>1</sup>David Geffen School of Medicine at UCLA, Los Angeles, CA, United States <sup>2</sup>Professor Emeritus of Medicine, Physiology and Biophysics, Medical School of the University of Southern California, Los Angeles, CA, United States

## Introduction

*Uremia* is conventionally defined as a condition due to an advanced insufficiency of the excretory function of the kidney (often called kidney failure) associated with the retention of urea and other products of cellular metabolism in blood and tissues. It is often accompanied by a diverse array of symptoms and signs affecting many organs and systems, called the *uremic syndrome*. *Azotemia* is a milder form of uremia, identified by an elevation of urea and other nitrogenous waste products in blood, that is not uncommonly asymptomatic.

As the overall function of the kidney declines in the course of chronic kidney disease (CKD), a wide variety of solutes derived from diet and endogenous metabolism that are normally dependent on glomerular filtration, tubular secretion or renal metabolism for elimination gradually accumulate in the body-fluid compartments [1–3]. Additionally, CKD is accompanied by a complex array of hormonal disturbances that lead to surfeits or deficiency in important biologically active molecules that can have marked effects on extrarenal organ function, such as bone, myocardium, nerves, and bone marrow. As pointed out by Zoccali and colleagues [3], CKD is a complex systemic disease, only partly explained by the accumulation of “uremic toxins.” To better understand CKD an integrated systems biology approach is needed, incorporating such elements as energy balance, innate immunity, and neuroendocrine signaling, which collectively generate a phenotype affecting many organs and systems.

In sum, retained or endogenously generated solutes have diverse biological effects that result in the malfunction of various subcellular organelles, cell types,

and organ systems. When these biological effects are sufficient to evoke clinically recognizable disturbances, the uremic syndrome (see Table 6.1) can be manifest and the offending molecules are collectively designated “uremic toxins” or “uremic solutes.” [1–3]. These uremic toxins exhibit a broad array of physicochemical characteristics and have systematically been investigated for many decades leading to an extensive catalog of potential compounds and molecular entities [1–3] (see Table 6.2).

A complete characterization of the catalog of uremic toxins has great utility in the design of approaches for their removal by dialysis; for ways to enhance their removal by nondialytic methods; for creation of interventions to prevent/mitigate their formation or to enhance their nonrenal disposal; and for synthesis of inhibitors of their adverse effects on cells for organ systems—all directed at subjects with advancing CKD or kidney failure. The analysis of the issues surrounding uremic toxicity requires a useful definition and synthesis of a classification of uremic toxins. This essay attempts to provide a succinct and update approach to classification of uremic toxins and to provide an integrated overview of their pathobiology [1].

## Definition of a uremic toxin

More than 4 decades ago, the late Jonas Bergstrom gave a definition of the uremic syndrome that is just as valid today as it was then [4]. He stated that the uremic syndrome is a “toxic syndrome caused by severe glomerular deficiency associated with disturbances in tubular and endocrine functions of the kidney. It is

**TABLE 6.1** Symptoms and signs of uremic toxicity (components of the uremic syndrome).

---

• Anorexia
• Nausea (especially in early morning)
• Vomiting
• Dysgeusia
• Uremic fetor
• Stomatitis
• Diarrhea
• Pruritis
• Urochrome pigmentation
• Uremic “frost”
• Onychodystrophy (“half and half” nails)
• Pallor (anemia)
• Vascular calcification (“ossification”)
• Periarticular calcium deposits
• Calciphylaxis
• Weakness
• Easy fatigability
• Protein-energy wasting
• Peripheral neuropathy—paresthesia (numbness/tingling in limbs)
• Carpal tunnel syndrome ( $\beta_2$ -microglobulin amyloidosis)
• Impotence
• Shortness of breath (anemia, uremic pulmonary edema, and pleural effusions)
• Chest pain (pericarditis/pleuritis)
• Easy bruising/bleeding gums
• Joint pain (gout and pseudogout)
• Joint destruction ( $\beta_2$ -microglobulin amyloidosis)
• Impaired cognition
• Sleep disturbances
• Drowsiness
• Seizures
• Coma

---

characterized by the retention of toxic metabolites, associated with changes in the volume and composition of the body fluids and an excess or deficiency of various hormones.” This very inclusive definition allows the uremic syndrome to embrace the retention of solutes due to failure of renal excretion (glomerular and/or tubular insufficiency) and hormonal surfeits or deficiencies arising from the disturbances wrought by kidney disease itself.

From this analysis, it is clear that uremic toxins must be defined via a causative link between the putative toxic substance and one or more of the pathophysiological manifestations of the uremic syndrome. Making this connection requires that a series of criteria be fulfilled, called the Massry/Koch postulates—so-called because they are a derivative of Koch’s postulates for defining a pathogenic organism, as developed by one of the coauthors of this essay (SGM), more than three decades ago [5]. These postulates establish the requirements for an “authentic” uremic toxin as follows:

1. The toxin must be identified and characterized as a unique chemical entity.

**TABLE 6.2** A catalog of the major organic uremic toxins.*Low molecular weight, polar (water soluble)*

- Guanidines (ADMA, GAA, GSA)
- Oxalates
- Phenylacetylglutamate
- Methylamine (TMA N-oxide)
- Sulfuric compounds
- Myoinositol
- 2PY
- Polyamines (putrescine, spermine)
- Urea (isocyanate)
- Carbamylated compounds
- Ammonia
- Uric acid
- Xanthines

*Protein bound, water soluble*

- Advanced glycation end products
- Advanced oxidation protein products
- CMPF
- Cresols (*p*-cresyl sulfate)
- Hippurates
- Homocysteine
- Indoles (indoxyl sulfate, kynurenes)
- Phenols (phenylacetic acid)
- Quinolinic acid

*Middle and higher molecular weight*

- Adrenomedullin
- Adipokines (adiponectin, leptin)
- Atrial natriuretic peptide
- $\beta_2$ -Microglobulin
- $\beta$ -Endorphin
- $\beta$ -Lipotropin
- Cholecystokinin
- Complement factor D or B
- Cystatin C
- Interleukins (1, 6, 8, 10)
- Tumor necrosis factor
- Endothelins
- FGF-23
- Ghrelin
- Glomerulopressin
- Parathyroid hormone
- Peptide YY
- Prolactin
- Resistin
- Visfatin

ADMA, Asymmetric dimethylarginine; CMPF, 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid; FGF-23, fibroblast growth factor-23; GAA, guanidine-acetic acid; GSA, guanidine-succinic acid.

Adapted from Vanholder R, Pletinck A, Schepers E, Glorieux G. Biochemical and clinical impact of organic uremic retention solutes: a comprehensive update. *Toxins (Basel)* 2018;10:pii. E33.

2. Quantitative analysis of the toxin in biological fluids must be possible.
3. The level of the putative toxin must be elevated in biological fluids of subjects with the uremic syndrome.

4. A relationship between the level of the putative toxin in biological fluids and one or more of the manifestations of the uremic syndrome must be present.
5. A reduction in the levels (or total body burden) of the putative toxin in biological fluids must result in some measurable amelioration of uremic manifestations.
6. Administration of the putative toxin to achieve levels similar to that observed in the uremic syndrome must reproduce the uremic manifestations in otherwise normal animals or man (in vitro demonstration of cellular toxicity alone is insufficient to meet this criterion).

A seventh criterion could be added to this list; that a consistent and plausible pathobiological mechanism should be able to explain the linkage between the putative toxin and the uremic manifestation (e.g., organelle dysfunction, inhibition of signal transduction, and metabolic perturbations). These postulates are difficult to apply directly to those disturbances that are part and parcel of the uremic syndrome but which emanate from deficiencies of certain hormones or biologically active peptides (e.g., erythropoietin, calcitriol) consequent to the loss of renal mass in CKD. Nevertheless, these postulates are quite useful for the definition of uremic toxins resulting from retention of solutes normally excreted by the kidney and substances that arise in enhanced levels endogenously (from excessive synthesis or impaired degradation) as kidney disease progresses to symptomatic uremia [e.g., parathyroid hormone (PTH)]. Obviously, diet per se is an important source of uremic solutes, but it is increasingly apparent that the intestinal microbiota play a very important role in endogenous generation of uremic solutes.

The demonstration of a causative linkage between a specific putative uremic toxin and a clinical manifestation of uremia can be a formidable task, as the symptoms and signs of “uremia” are extraordinarily diverse [6] (see Table 6.1), affecting many organs and systems. The ability of a specific putative toxin to elaborate a clinical manifestation is governed by a panoply of factors (see Table 6.3). These facts complicate enormously the task of identifying “authentic” uremic toxins as they require both longitudinal and cross-

sectional analysis, body-fluid compartmental studies, and the influence of naturally occurring inhibitors and promoters. Some toxins may also exhibit “tropism” for specific cellular types or organ systems (e.g., neuro-tropism) (see next).

### **Classification of uremic toxins by physicochemical characteristics**

An examination of putative uremic toxins according to their physicochemical characteristics (molecular mass, polarity, protein binding, and chemical structure) has been the time-honored and the most popular approach to their physicochemical classification [1–3]. In this schema, uremic toxins are categorized into four nonoverlapping categories: (1) polar, water soluble, nonprotein bound, and low molecular mass (<500 Da); (2) polar, water soluble, protein bound, and low molecular mass (<500 Da); (3) middle-molecular mass (>500 and <3000–12000 Da) and nonprotein bound; and (4) high-molecular mass (>3000–12,000 Da) and nonprotein bound [1–3]. The pioneering work of the European Uremic Toxin Work Group (EUTox) has been invaluable in creating a uniform approach to classifying uremic toxins and has pointed out the necessity for standardized schema for analysis of their in vitro effects and the enormous difficulties posed by variability in reported concentrations of putative toxins [2]. In their landmark initial review the EUTox group created an encyclopedic listing of uremic retention solutes (90 total), 68 of which were <500-Da molecular mass, 10 had a molecular mass of >500–12,000 Da, and 12 had a molecule mass of >12,000 Da. A total of 25 of the retention solutes were protein bound; all but 2 of these had a molecular mass of <500 Da. The concentration of these putative toxins in biological fluids ranged broadly from ng/L to g/L. Of all the toxins identified, almost 40% were either “middle” molecules or protein bound. Larger molecular-weight compounds (molecular weight between 16 and 60 kDa) represent a major challenge as many dialytic procedures are quite inefficient for their removal [7,8]. The “middle molecule” hypothesis of Babb and Scribner rests on the notion that molecules of 500–2000 Da can be responsible for the signs and symptoms of uremic

**TABLE 6.3** Factors determining the toxicity of substances accumulating in uremia.

- The time-related evolution of the levels of putative toxins in biological fluids, for example, time-averaged vs peak levels cellular penetration into sites of action (cytoplasm, endoplasmic reticulum, mitochondria, nucleus)
- Metabolism to more (or less) toxic compounds
- Distribution in body fluids (protein binding, lipophilicity, hydrophilicity)
- Presence of naturally occurring inhibitors or promoters
- Rates of metabolism of putative toxins

*Adapted and updated from Glascock RJ. Uremic toxins: what are they? An integrated overview of pathobiology and classification. J Ren Nut 2008;18:2–6.*

toxicity (such as peripheral neuropathy), and their removal by dialysis is an important consideration in dialytic therapy of kidney failure [9–11]. Peritoneal dialysis may have a better profile of removal of higher molecular-weight solutes or protein-bound solutes, but this may not necessarily translate to better outcomes for peritoneal dialysis compared to hemodialysis [12]. However, formal testing of the added value of assessing the serum concentration of a given protein-bound solute for improving the dialysis prescription is largely lacking [13]. Such testing is sorely needed, in the authors' opinion.

The development of large-scale, rapid capillary electrophoresis—mass spectrometry, proteomic, and metabolomic analysis of body fluids—has greatly enhanced the ability to identify and characterize potential uremic toxins [14–18] (see Table 6.2). This original compendium from 2003 has been updated by Duranton and coworkers in 2012 [19] and by Vanholder and coworkers in 2018 [20]. Collectively, these studies demonstrated “uremic solute” serum concentrations in subjects with CKD, with many claims based on single reports (i.e., not reduplicated). Overall, 52 of 88 uremic solutes studied were based on single reports. Among those solutes based on multiple reports (total  $n = 27$ ), 26% were low molecular weight and water soluble; 26% were protein bound; and 48% were middle or higher molecular weight. Importantly, some compounds defined as “uremic” solute had normal serum concentrations in patients with advanced kidney disease. A scoring system has been developed by Vanholder et al. [20] to categorize the strength of the association of the uremic solute to toxicity. The highest scores were found with three small water-soluble solutes [asymmetric dimethylarginine (ADMA), trimethylamine N-oxide (TMAO), and uric acid], six protein-bound solutes [AGEP, *p*-cresyl sulfate (pCS), indoxyl sulfate (IS), indole acetic acid, kynurenines, and phenylacetic acid], and three middle-molecular-weight compounds ( $\beta_2$ -microglobulin, ghrelin, and PTH). They concluded their extensive 2018 narrative review with a very telling statement:

“the picture emanating is one of a complex disorder, where multiple factors contribute to a multisystem complication profile, so that it seems of not much use to pursue a decrease of concentration of a single compound [20].”

Inorganic substances ( $\text{H}_2\text{O}$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{K}^+$ ,  $\text{H}^+$ ,  $\text{Mg}^{++}$ ,  $\text{PO}_4^-$ ,  $\text{Ca}^{++}$ , and  $\text{SO}_4$ ) and trace elements [e.g., Al, Cr, Se, Pb, Cu, and Cd (see next)] can also qualify as uremic toxins. For example, the retention of sodium chloride and water can evoke volume expansion and disastrous consequences on the cardiovascular system in CKD and end-stage renal disease (ESRD) and contribute markedly to organ dysfunction (left ventricular

hypertrophy), morbidity (hypertension and congestive heart failure), and mortality (sudden cardiac death) (see also next) [21]. However, dietary salt excess and salt retention can also have many body fluid-independent effects on the vascular system, including fostering an inflammatory milieu [22,23]. Also, metabolic acidosis (retention of  $\text{H}^+$  ion) can wreak havoc in many cell and organ systems (such as bone and myocardium), and metabolic acidosis can itself perpetuate the progressive nature of CKD [24]. Divalent ions such as phosphate and calcium also participate in homeostatic disturbances associated with uremia [25]. These are discussed in more detail in Chapter 17, Disorders of Phosphorus Homeostasis: Emerging Targets for Slowing Progression of Chronic Kidney Disease, Chapter 23, Calcium, Phosphate, PTH, Vitamin D, and FGF-23 in CKD-Mineral and Bone Disorder, and Chapter 24, Phosphorus Metabolism and Fibroblast Growth Factor 23 in Chronic Kidney Disease. Trace elements (such as aluminum, lead, iron, selenium, strontium, silicon, copper, cadmium zinc, rubidium, molybdenum, and tin) have been studied for decades [26–30]. Although many of these elements can be increased in uremia, some are depleted (such as zinc and selenium) [29]. Some, such as aluminum, are increased in tissues and serum because of medication (aluminum-containing phosphate binders) or environmental exposure (contaminated water-cooking vessels) and can produce specific clinical abnormalities, such as aluminum intoxication, causing neurological abnormalities and aplastic bone disease [28]. Dialysis fluids can also serve as a source for an increased burden of trace metals [26].

Although many potential uremic toxins are elevated in plasma due to impairment of renal excretion, many are also associated with increased synthesis or impaired degradation of normal substances produced endogenously [e.g., PTH, and fibroblast growth factor-23 (FGF-23)]. It must be emphasized that the plasma concentrations of putative uremic retention solutes are very poorly correlated with the prevailing level of estimated glomerular filtration rate (eGFR) [31–35], and the plasma levels of each specific solute may have a unique association with the level of eGFR [34]. These data point out the major limitations of eGFR as a predictor of uremic solute concentrations [33]. These observations also add emphasis to a neglected phenomenon well-recognized in the aglomerular kidney of marine teleosts (i.e., anglerfish) [31], specifically that the tubules represent an important site for the elimination of putative toxic by-products of metabolism. This phenomenon was pointed out in an elegant essay by Jerome Lowenstein in 2011 [31].

Thus residual activity of transport systems in tubules of diseased kidneys [most specifically the

organic anion transporters (OAT) in the proximal tubule] may have an important influence on the concentration of toxins at low levels of GFR [33–35]. This phenomenon gives rise to the notion that enhanced expression of the OAT might be able to limit the accumulation of uremic toxins even with advanced loss of GFR [1]. The kidney clearance of organic solutes secreted into the proximal tubule is strongly negatively associated with the degree of decline of eGFR in CKD [36]. Nevertheless, among pediatric patients undergoing maintenance hemodialysis (MHD) for ESRD, the serum levels of protein-bound solutes appear to be linked to the prevailing level of residual renal function and urine volume [33].

The low-molecular-mass solutes (<500 Da) have attracted a great deal of attention over many years. Urea (molecular weight 60 Da) is nonprotein-bound solute that has been used as a “surrogate” for “authentic” uremic toxins, although its intrinsic toxicity is greatly limited to very, very high plasma concentrations seldom achieved even in advanced uremia [37]. The evidence that urea per se functions as an authentic uremic toxin is very weak [37,38]. Nevertheless, its spontaneous degradation to isocyanate can lead to the carbamylation of serum and tissue proteins, such as albumin or hemoglobin, and amino acids. High urea concentrations in biological fluids can lead to insulin resistance, free radical production, cellular apoptosis, and disruption of the protective intestinal barrier—all linked to pathobiological changes seen with uremic toxicity [39]. Urea is an attractive “surrogate” marker of uremic toxicity as it is fundamentally derived from catabolism of dietary and endogenous somatic proteins. Urea is produced by the catabolism of endogenous or dietary proteins. In the intestine, it degrades to ammonia and CO<sub>2</sub> by the actions of bacterial urease. The ammonia can traverse to the liver, via the portal vein, and be reutilized for urea (or protein) synthesis by the liver. [40]. This extrarenal clearance of urea seems to be reduced in uremia [40], but due to the elevated plasma urea the formation of ammonia nitrogen from urea degradation is about the same in uremic and normal subjects (about 3.5 g/d) [40]. The administration of alpha-keto analogs of valine, leucine, isoleucine, methionine, and phenylalanine along with other essential amino acids can, at least in some uremic subjects, diminish the rate of urea appearance in plasma and body fluids perhaps by augmenting nitrogen conservation and reutilization or by promotion of net protein synthesis [41] (see also next).

The metabolism of amines, such as dimethylamine, trimethylamine, spermine, and putrescine, is disturbed in uremia and many amine compounds accumulate in plasma of uremic subjects [42], largely as a consequence of the actions of the intestinal microbiota.

TMAO, an oxidation product of trimethylamine derived from choline, is synthesized by the intestinal microbiota metabolism of constituents of meat, including carnitine or lecithin, and may also be an important low-molecular-weight uremic toxin (see also next). The metabolism of phenylalanine and tyrosine is also disturbed in uremia, leading to increase plasma levels of phenylacetic acid, *p*-hydroxyphenylacetic acid, *p*-hydroxybenzoic acid, and phenylpyruvic acid in uremia [43].

Protein-bound uremic toxins are of great theoretical and practical importance [44–47]. Such protein binding may greatly limit the ability of diffusive or convective dialysis therapies to remove the compound efficiently, and this explains the limitations of extracorporeal therapies using membranes of low-molecular-mass “cutoff” for the treatment of uremia. Displacement of the uremic toxin from its protein-binding site (e.g., on albumin) might be a very attractive way of enhancing uremic solute removal by dialysis. For example, a recent study by Madero and coworkers has shown enhanced dialytic removal of protein-bound solutes by the infusion of ibuprofen (a competitive albumin binding inhibitor) into the arterial bloodline [48] (see also next).

The best studied of the protein-bound uremic solutes include pCS and IS [47,49,50]. Both of these uremic solutes originate in the colon from the action of resident bacteria—the intestinal microbiota on the amino acid tryptophan [51]. Thus there is an important contribution of the colon to the uremic state [52–54]. Urea retention and other uremic solutes can lead to a dramatic alteration in the intestinal microbiota (the gut microbiome) [52–54]. The colon contains abundant nitrogenous compounds, many of which accumulate in the plasma of subjects with kidney failure and, therefore, qualify as potential uremic toxins [52,53]. Many of these are sulfated conjugates that are excreted normally by a combination of glomerular filtration and secretion by the proximal tubule [52,53]. Decreases in beneficial bacteria that provide nutrients to the intestinal epithelium are seen along with an increase in bacteria that synthesize damaging uremic toxins (such as pCS, IS, and TMAO) [54,55]. There is an important interaction of the enterohepatic cycle of bile acid metabolism and the gut microbial flora (reviewed in Ref. [56]) and these participate in the intestinal generation of uremic solutes. Local inflammation degrades the intestinal epithelial barrier function, and these toxic solutes are generally translocated from the intestinal lumen to the bloodstream, where they may have adverse effects on vascular calcification, cardiovascular function, atherogenesis, red blood cell generation, fibrosis, and immune dysfunction [57]. These phenomena provide a rationale for treatment of uremia by oral adsorbents [58], such as activated charcoal (AST-120; Kremezin) [58]

or sevelamer [59] or by probiotics [60]. The oral absorbent Kremezin seems to have beneficial effects on lowering IS levels, but sevelamer has no substantial effect on either pCS or IS levels. Despite initially promising reports, Kremezin has inconsistent effects on CKD progression [58]. Interventional trials of the use of probiotics are still lacking [60]. Some studies have shown that pCS and IS promote vascular calcification and impair glucose tolerance in experimental animals [61]; however, in a large clinical trial of MHD patients (the HEMO study), a post hoc analysis suggested that neither pCS nor IS was associated with adverse cardiovascular outcomes [62]. In addition, recent studies have shown that hemodiafiltration is no better than hemodialysis for the removal of protein-bound uremic solutes [63] (see also next). Tryptophan-derived uremic solutes (such as IS) may have prothrombotic effects [64].

Other protein-bound uremic solutes include ADMA, homocysteine, nucleosides, and pentosidine. ADMA appears to accumulate in uremia more as a result of disturbed renal metabolism than from impaired renal excretion [65–68]. It is noteworthy that the  $R^2$  value of ADMA levels in relationship to eGFR is only 0.167 (the  $R^2$  value to creatinine is 0.737) [19,20]. Uric acid and other nucleotide derivatives are emerging as important candidates for low molecular mass uremic toxins [69,70]. Cellular mitochondria might serve as a source as well as a target of uremic toxins [71], thereby establishing a “vicious cycle” of positive feedback. Deoxyglucosone and advanced glycation end products may accumulate in uremia [1,2]. Thus several carbohydrate-derived moieties can contribute to the uremic state.

Middle molecules (>500–12,000 Da) have been regarded as important to the uremic syndrome and to the response of uremia to dialysis treatment ever since the seminal observations leading up to the “middle molecule hypothesis” were made by Babb and Scribner 45 years ago [72]. As noted earlier, EUTox identified about 10 such middle molecule uremic toxins in their initial survey [2,19,20]. These compounds are often glucuronide conjugates, polypeptides (such as  $\beta_2$ -microglobulin), carbohydrate derivatives, advanced glycation or oxidation end products (AGEP/AGOP), or polypeptide hormones (such as parathyroid hormone (PTH) or its fragments, or fibroblast growth factor 23 (FGF-23)) [73,74].

$\beta_2$ -Microglobulin (molecular weight 11.8 kDa) has attracted a great deal of attention. It is a constituent of the HLA (human leukocyte antigen) molecule located on the cell surface of all nucleated cells and is shed into the circulation at a relatively constant rate of about 50–200 mg/d, under normal noninflammatory conditions. The kidney is the major route of elimination for  $\beta_2$ -microglobulin so it accumulates in the

plasma of patients with CKD and, because of its size, is poorly removed by standard dialysis [75–78]. Its toxic properties are due to the propensity to aggregate and form a misfolded protein with a  $\beta$ -pleated sheet ( $\beta_2$ -microglobulin amyloidosis) that preferentially deposits in large bones close to articular surfaces, synovial membranes, and carpal tunnel tissue, causing pain, bone destruction, malfunction, and disability. It is mainly seen in patients of late vintage hemodialysis (usually >8 years). The use of high-flux, biocompatible membranes can reduce the likelihood of these complications, via enhanced removal of  $\beta_2$ -microglobulin (see next). The incidence of  $\beta_2$ -microglobulin-related amyloidosis has been decreasing, probably because of wider use of biocompatible high-flux membranes, but prolonged survival of dialysis patients may offset this phenomenon [76–78].

PTH is the quintessential prototype of a high-molecular-weight uremic toxin. As stated earlier, it is one of only a very few uremic toxins that have fulfilled the Massry/Koch postulates. Intact (native) PTH has a molecular weight of 9.5 kDa, but in CKD both the intact hormone and metabolic fragments circulate. Elevated levels are virtually always seen in CKD, beginning at about Stage III. This is largely due to increased secretion caused by disordered homeostatic control (secondary hyperparathyroidism). The increased intact biologically active PTH (and its fragments) in CKD [79] can result in a plethora of manifestations, including osteitis fibrosa cystica (high-turnover bone disease) [80], impaired erythropoiesis (due to bone marrow fibrosis) [81], shortened red cell survival [82], cutaneous and subcutaneous calcific deposits [83], myocardial injury [84,85], leukocyte and immune cell dysfunction [86], impaired glucose homeostasis, and reduced insulin secretion [87] and defects in neuronal transmission [88] (reviewed in Ref. [89]). Many of these manifestations are linked to an increase in cytosolic calcium concentrations, but multiple mechanisms may contribute to these effects [90]. Lowering of serum PTH levels in uremia may prevent or ameliorate many of these uremic manifestations, particularly those involving bone (fractures, pain) and soft-tissue calcifications.

FGF-23 is another emerging candidate for a middle-molecular-weight uremic toxin [91–93]. It is a phosphaturic peptide hormone (molecular weight of 32 kDa) derived from the bone osteocyte that plays a central role in mineral metabolism by the regulation of renal phosphate handling, vitamin D metabolism, and PTH secretion (see earlier) [91–93]. Its function in the kidney depends upon a cofactor  $\alpha$  Klotho, but it has many Klotho-independent extrarenal effects, especially on the myocardium [91–93], where it may induce

myocardial hypertrophy. Serum levels of FGF-23 rise early in CKD and may have deleterious, Klotho-independent effects on myocardial function (uremic cardiomyopathy) and inflammation [91–93]. However, studies of FGF-23 in hemodialysis patients have challenged this hypothesis [94] (see also next).

The other high-molecular mass (> 12,000 Da) nondialyzable toxins have been less well characterized and include cytokines, chemokines, Ig light chains, complement factors, AGE/AGOP, inhibitor proteins, and chemotaxis-inhibiting peptides [1,2] (see Table 6.2).

### **The pathobiologic categorization of uremic toxins according to the processes underlying accumulation in body fluids**

Uremic toxins can accumulate in body-fluid compartments through a number of distinct mechanisms. A *Type I* mechanism represents the accumulation in body fluids of toxic substances normally produced *endogenously* by metabolic processes, including those that occur in intestinal microbiota, largely as a result of reduced renal excretory capacity (decreased GFR and/or tubular excretory function). A *Type II* mechanism is a surfeit of toxic substances in body fluids as a result of excess *endogenous* production or impaired degradation (or both) but not necessarily *directly* due to reduced renal excretory capacity. A *Type III* mechanism is the accumulation of toxic substances in biological fluids from *exogenous* sources by virtue of reduced renal excretory capacity often combined with continued usual dietary consumption. A *Type IV* mechanism is a deficiency or reduced activity of substances normally produced *endogenously* as a result of decreased synthesis, enhanced degradation, or biological inhibition. Combinations of more than one pathobiological process are possible. For example, urea is a putative uremic toxin that arises because of a combination of *Type I* and *Type III* processes—excessive accumulation due to impaired renal excretion and continued production due to exogenous (dietary) consumption of protein as a precursor of urea. These categories of pathobiological process are not mutually exclusive, and one may predominate over another in certain circumstances. As outlined earlier, dysbiosis of the intestinal microbiota is a very important contributor to the pathobiology of uremia, and is embraced in the *Type I* mechanism. PTH excess in CKD is a prime example of a *Type II* uremic toxicity. It is helpful to keep this classification of the processes underlying accumulation of uremic toxins in mind when approaching a patient with the uremic syndrome.

### **The linkage of uremic toxins to the pathobiology of uremia**

In recent years a new concept has emerged that the uremic syndrome is strongly associated with a state of “chronic inflammation” and enhanced “oxidative stress” accompanying CKD that are manifested by an increase in “positive” acute-phase reactant proteins (such as C-reactive protein (CRP), Interleukin-6 (IL-6), fibrinogen, ferritin, and serum amyloid A protein) and a reduction in “negative” acute-phase reactant proteins (albumin, transferrin, and prealbumin) [1]. The proposed origins of this inflammatory state include: (1) an imbalance in the body between pro- and antiinflammatory factors, (2) underlying organ-based chronic inflammation (occult infection, e.g., periodontal disease, infected vascular access, vulnerable lipid-rich atherosclerotic plaques, and localized intestinal inflammation consequent to dysbiosis, kidney inflammation associated with the underlying disease) [95], and (3) exposure to inflammatory promoters (endotoxin contaminated dialysate, bioincompatible membranes). No doubt in individual patients, multiple factors explain the presence of an inflammatory state. Certain candidate uremic toxins, such as uric acid or ADMA, may be potent promoters of inflammation. In turn, inflammation can lead to the generation of uremic toxins, such as advanced oxidation products, via the generation and inadequate scavenging of toxic oxygen radicals [1]. IS can also promote further progression of renal disease by activating harmful mediators such as Transforming growth factor beta (TGF beta) [1]. Thus the accumulation of uremic toxins may also exert a positively reinforcing action on the basic process of tissue and organ damage, in addition to contributing to the manifestations of the uremic syndrome *per se* [1].

The “toxicity” of ADMA has also emerged as an important element in new concepts of the pathobiology of uremia [1]. This methylated amino acid is highly protein bound, and its concentration in plasma is elevated in uremia. The elevation is predominantly caused by the inhibition of its major kidney-derived metabolizing enzyme (dimethylarginine dimethylaminohydrolase-1; DDAH-1) rather than by markedly decreased renal excretion. ADMA, along with uric acid, is a potent inhibitor of endothelial cell nitric oxide synthase (eNOS) [1]. Impaired eNOS and reduced nitric oxide production by endothelial cells may lead to vasoconstriction, elevated blood pressure, and vascular damage. Oxidative stress associated with uremia may also impair the effectiveness of DDAH-1 providing a link between endothelial cell dysfunction and inflammation in uremia [1]. DNA methylation and repair may also be adversely affected by putative uremic toxins [1]. Thus some retention uremic solutes (such as homocysteine

and its metabolites) could have profound effects on gene expression and epigenetics [96].

TMAO has received substantial attention as a low-molecular-weight, polar uremic solute that promotes cardiovascular disease [97–100]. This molecule is generated from choline, betaine, and carnitine consequent to gut microbial action [101]. The blood levels are determined by diet (especially red meat) [99], the gut microbiome, drugs, and hepatic Flavin monooxygenase activity. Increased plasma levels are associated with enhanced atherogenesis and an increase in cardiovascular events. Omnivores have higher plasma levels of TMAO than vegetarians. Dietary L-carnitine (in red meat) rapidly generates  $\gamma$ -butyrobetaine that is then converted by microbiota to TMA and thence to TMAO [99]. Thus TMAO may be a significant uremic toxin that may be subject to manipulation by dietary interventions. Interestingly, TMAO may protect cellular proteins from the damaging effects of carbamylation from urea [100].

Thus the pathobiology of uremic toxicity needs to be viewed as a complex, dynamic, interacting system of effector, promoter, and inhibitory molecules occurring in a situation of reduced renal excretory capacity, impaired defensive ability, and superimposed deficiency states [3]. The cumulative adverse effects on cellular and organ system function will depend on the balance of these factors.

### Clinical manifestations of uremia and the role of tropisms

The clinical manifestations of uremic toxicity are broad and diverse. As pointed out previously, every organ system in the body can be affected. Each individual uremic toxin may have its own unique profile of “tropisms,” that is, each toxin may have a preferential action on only one system (monotropic) or may act on only a few systems (oligotropic). Most uremic toxins studied so far have effects on multiple systems (pleiotropic), perhaps by interference with very fundamental common pathways of cellular behavior or organelle function (nitric oxide synthesis, DNA methylation and repair, defense against oxidative stress, and mitochondrial dysfunction), such as best exemplified by PTH, uric acid, and other derivatives of purine nucleotides and ADMA. However, some toxins, such as guanidino compounds, may exhibit relative specificity for certain organ systems (hematopoiesis, neuronal function, bone metabolism, and endothelial cell integrity) [101]. Oxidized lipids, TMAO, and adipokines may have more deleterious actions on the vascular tree and insulin signaling [102,103]. Protein-bound toxins may have a predilection to produce damaging effects on the heart and cardiovascular system [104–107].

FGF-23 seems to have a major toxic effect on the myocardium [91–93], leading to left ventricular hypertrophy. Elucidation of the “tropic” behavior of individual uremic toxins is an important element in their full characterization and classification.

### The effects of diet and dialysis on uremic toxins

Uremic toxins consist of a panoply of molecules, some of which are derived from dietary intake (mainly its protein constituents) and the effects of the bacterial flora (microbiome) of the gastrointestinal tract on orally ingested nutrients. Thus it is not surprising that these factors can influence the circulating levels of at least some uremic toxins. Similarly, extracorporeal/extrarenal elimination of some uremic toxins is one of the fundamental tenets of dialytic treatment of the uremic state. This section will briefly summarize current knowledge concerning the impact of these two facets of uremia and uremic toxins

#### Diet

Plasma concentrations of low-molecular-weight uremic solutes (such as urea and guanidino compounds) are increased in CKD, and the levels correlate with dietary protein intake and urine urea nitrogen excretion [108]. The uremic solutes (often protein bound in the circulation) that are derived from the effects of the intestinal microbiome (pCS, hippuric acid, IS, phenylacetylglutamine, and TMAO) are increased even in moderate CKD, but the intake of dietary precursors or adherence to special diets have varying effects on plasma levels of these uremic solutes [109,110]. A plant-based diet may increase the levels of these solutes and agents that influence the microbiome (probiotics, prebiotics, and synbiotics) and may decrease the levels of at least some uremic solutes, such as IS [110,111]. A low-protein diet (0.6 g/kg/d) can reduce levels of pCS and IS, possibly by influencing the gut microbiome profile [112]. Genetic modulation of gut microbiota can influence circulating uremic toxin concentrations directly [113]. This latter evidence strongly points toward the controlling effects of the gut microbiota on circulating uremic toxin levels in CKD. The characteristics of the gut microbiota are in turn influenced by the diet, especially protein and fiber [114]. Vegetarians consuming a low-protein, plant-based diet have lower production of *p*-cresol sulfate and IS compared to omnivores on a normal protein intake [115]. This has led to an increasing number of proposals for a low-protein, plant-based diet as the preferred one for patients with CKD [116,117]. However, these proposals

have not yet been formally tested for efficacy in large randomized prospective clinical trials. Moreover, when careful plasma, urine, and fecal studies are performed in subjects at varying stages of CKD, the differences in plasma protein-bound uremic toxin levels cannot be explained by the generation rate by gut microbiota, suggesting that retention consequent to reduced kidney function is the main determinant of increased plasma concentrations of protein-bound uremic solutes [118]. This may not apply to all solutes and does not mean that efforts to reduce the intestinal generation of uremic toxins are without merit. As mentioned earlier, administration of alpha-keto analogs of essential amino acids along with a very low-protein diet may have salutary effects on low-molecular-weight toxin levels, but the overall value of this approach to management of the uremic syndrome needs much more investigation [119]. The excess dietary or medication intake of trace elements may have a deleterious effect on uremic manifestations. As stated earlier, aluminum is the classic example

## Dialysis

No doubt exists that dialysis (hemodialysis or peritoneal dialysis) can remove low-molecular-weight, water-soluble, nonprotein-bound uremic solutes (such as urea or creatinine), and this serves as the basis of  $K_t/V$  (urea) as a standard measure of dialysis “adequacy.” The situation is much less clear for protein-bound uremic solutes (reviewed in Ref. [120]). Protein-bound uremic solute levels in dialysis-treated ESRD patients are mainly related to residual renal function and are not influenced by the convective transport of dialysis [121,122]. A small short-term trial has shown only very limited impact on protein-bound uremic toxin levels when low-flux, high-flux, and postdilution hemodiafiltration are compared [123]. Techniques to enhance dialysis removal of protein-bound uremic solutes by the use of competitive inhibitors of binding are under investigation [48,124]. Reduction of uremic toxins by dialysis is important, as many of these chemicals have direct cardiovascular toxicity (such as TMAO and IS) [125]. So far, long-term outcomes on dialysis are not greatly influenced by levels of protein-bound solutes, the plasma levels of which seem to be largely governed by residual kidney function.

The use of medium cutoff dialysis membranes or hemodiafiltration improves the removal of middle molecules, such as  $\beta_2$ -microglobulin and free light chains, but the long-term beneficial effects of this treatment are uncertain, at best [126,127]. As stated previously, the occurrence of  $\beta_2$ -microglobulin

amyloidosis in hemodialysis patients has been decreasing in recent decades but has not entirely disappeared [76–78].

The association of persisting volume excess (fluid overload) in kidney failure treated by dialysis with all-cause and cardiovascular mortality [128] may point to an important “uremic toxicity” effect of retained sodium and water as compared to the traditional view of “uremic toxicity” as a manifestation of retention of protein-related metabolites, exogenous or gut derived [129]. Removal of trace elements by dialysis is largely inconsequential, although iron, selenium, and zinc deficiency can occur and iron overload may develop from repeated blood transfusions or excess oral or parenteral iron. Technically, these are not uremic toxins, per se.

## Summary and conclusion

An exposition of uremic toxicity requires an integrative analysis of the physicochemical properties of putative toxins (molecular size, polarity, and protein binding), an understanding of the pathobiological processes responsible for their formation and accumulation, and a mechanistic view of how they alter fundamental cellular and organ behavior. A consideration of both glomerular filtration and tubular secretion is essential for the proper understanding of levels of putative uremic toxins in the body fluids in CKD and ESRD. An explanation of how individual toxins or groups of toxins lead to clinical manifestations of uremia requires a consideration of tropism (monotropic, oligotropic, and pleiotropic toxins). This “multidimensional” integration allows for a better understanding of the complexity and the potential for mapping of the important elements of uremic toxicity. The long-term importance of a better understanding of the chemical basis of uremia is to aid the development of more effective and more rational methods of treatment, including dietary manipulation to minimize formation of toxins, ablation of organ sources of putative toxins, reduction of exogenous sources of toxic precursors, reduction in (colonic) formation, and absorption of putative toxins derived from actions of intestinal microbiota on dietary constituents (mainly proteins), enhancement of extrarenal removal of toxins (intra- or extracorporeal), supplementation for replacement of deficiencies, suppression of toxic effects at the cellular level, and replacement of renal tissue or its products. The specific roles of retained uremic toxins, derived from diet and gut metabolism, as compared to retention of sodium and water (volume overload) need to be better understood. Dietary and dialytic management of uremic toxicity is but one part of the overall picture of uremic therapeutics. Note added in Proof—Very recently, an International Consensus Conference (see Reference [130])

has revised and updated the definition and classification of uremic toxins. This timely and very comprehensive schema has been based on a “holistic” integration of the physico-chemical characteristics and dialytic removal of the solutes retained in uremia. The focus is on linkage with clinical findings and outcomes, particularly in kidney failure treated by hemodialysis. An evidence based approach is emphasized. Recommendations for future research is also included in the presentation. This landmark conference publication is worth reading in its original form.

## General considerations

Inflammation (Latin *inflammatio*, to set on fire) represents a complex biological response of vascular tissues to harmful stimuli. Acutely, inflammation may be considered a protective attempt by the organism to remove the injurious stimuli as well as to initiate the healing process. Whereas the acute release of proinflammatory cytokines may have beneficial effects, a chronic low-grade systemic inflammatory activity is likely to be detrimental for the organism. This is the problem faced in the uremic milieu, characterized by a state of persistent low-grade chronic inflammation, and where the persistent effect of causative stimuli leads to functional changes as well as destruction of cells and tissues.

In chronic kidney disease (CKD) and especially in end-stage kidney disease (ESKD) the systemic concentrations of both pro- and antiinflammatory cytokines are multifold higher, due to both decreased renal clearance and increased tissue production. Because of this, inflammation is a major characteristic in advanced CKD worldwide according to C-reactive protein (CRP) estimations [1–8]. Reports from the National Health and Nutrition Examination Survey III show that half of the patients with estimated glomerular filtration rates 15–60 mL/min had CRP levels >2.1 mg/L [9]. Among ESKD patients undergoing dialysis, significant geographic variation exists with Asian patients showing markedly lower inflammation compared to those from either Europe or North America (Fig. 7.1) [1–8]. Effects of chronic inflammation, via both direct and indirect mechanisms, are an important inducer of the protein-energy wasting (PEW) syndrome, cardiovascular disease (CVD), and mineral and bone disorder. The purpose of this

chapter is to describe the physiopathology and implications of these complex inflammatory processes with a special focus on PEW. At the same time, we will discuss the applicability of regular CRP monitoring in the clinical setting and possible therapeutic initiatives to tackle this risk factor.

## Multifactorial causes of inflammation in chronic kidney disease

There are many and varied factors, inherent or not to a reduction in kidney function, that contribute to systemic inflammation. Among these, intercurrent clinical events are likely the most important [10]. Infectious agents and microorganisms are also causative or contributory factors to the inflammatory cascade, being also associated with atherosclerosis progression [11–14]. Reductions in kidney function per se, or even small changes in residual renal function (RRF), further seem to impact on “uremic inflammation.” It has, thus, been hypothesized that retention of circulating cytokines [15], advanced glycation end products (AGEs) [16], and prooxidants [17] initiate and enhance the proinflammatory milieu when kidney function declines. Additional mechanisms by which a failing kidney function may promote inflammation include volume overload, carbonyl stress [18], metabolic acidosis [19], sympathetic overactivity (and/or blunted vagal nerve activity) [20], or chronic inflammatory process associated with periodontitis [21,22].

There is also a growing body of evidence that shows alterations in the gastrointestinal tract are an important source of inflammation [23]. The intestinal microbiota is involved in the regulation of the immune system

FIGURE 7.1 Distribution of CRP in different countries from the DOPPS study, restricted to patients on dialysis >90 days in facilities that routinely measure CRP ( $n = 4586$ ). The top and bottom of the boxes indicate the 25th and 75th percentiles of the distribution. The horizontal line within the box indicates the median (50th percentile), and the diamond indicates the mean. Vertical lines extend to the 5th and 95th percentiles. and is altered in patients with CKD and ESKD [24,25]. These alterations include a shift toward bacteria involved in the production of uremic toxins, including indole (i.e., indoxyl sulfate) and p-cresol sulfate. Furthermore, patients with CKD have reduced intestinal barrier function [26] that may increase bacterial and endotoxin translocation [27–30] and result in a strong immune response [28]. Fluid shifts and intestinal ischemia during hemodialysis (HD) may also exacerbate this translocation [31].

The HD procedure per se may further contribute to increased systemic inflammation [32] through interaction of circulating monocytes with nonbiocompatible membranes [33], blood contact with nonsterile dialysate solution [34], use of unpure dialysate [35–37], sodium tissue loading [38], the extent of convective transport, and the frequency and duration of dialysis [39,40]. However, the overall contribution of the dialysis procedure is unlikely a major instigator of inflammation because of the high prevalence of inflammation biomarkers in CKD 5 patients not yet on renal replacement therapy [41,42]. Overhydration and volume overload may, via bacterial or endotoxin translocation in patients with severe gut edema, lead to immunoactivation and increased inflammatory cytokine production [43]. Finally, strong interrelations between inflammation, RRF, and left ventricular hypertrophy have been documented in dialysis patients [4].

Obesity, a common finding in CKD patients, may also contribute to an enhanced inflammatory activity. Both truncal fat mass [44] and abdominal fat deposition [45] have been associated with increased systemic inflammation in dialysis patients. Also in nondialyzed CKD patients, longitudinal variations in abdominal fat are accompanied by parallel changes in systemic inflammation (Fig. 7.2). The reasons for this association

FIGURE 7.2 Direct association between 1-year variation in waist circumference and CRP levels in CKD patients stages 3–4. CKD, Chronic kidney disease; CRP, C-reactive protein. Source: Reproduced with permission from Carvalho et al., *Nephrol Dial Transplant* 2012;27:1423–8.

relate to the capacity of adipocytes and fat-infiltrated macrophages to secrete adipokines, interleukin (IL)-6, or tumor necrosis factor (TNF)- $\alpha$  into systemic circulation [46,47]. Many adipokines exert further proinflammatory effects [48–50]; considering the dramatic effect that loss of RRF has on the clearance of adipokines, the systemic effects of adipokine imbalance in CKD patients may be even greater than in the general population. Furthermore, uremic fat may be overactivated, since proinflammatory genes have been demonstrated to be upregulated in visceral fat from CKD patients as compared to matched controls [51]. Surprisingly, a recent observational study found that the protective effect of higher BMI on mortality existed in inflamed, but not noninflamed dialysis patients [52]. As a final remark, we should emphasize that obesity, as a proinflammatory state, may also link to PEW. The concept

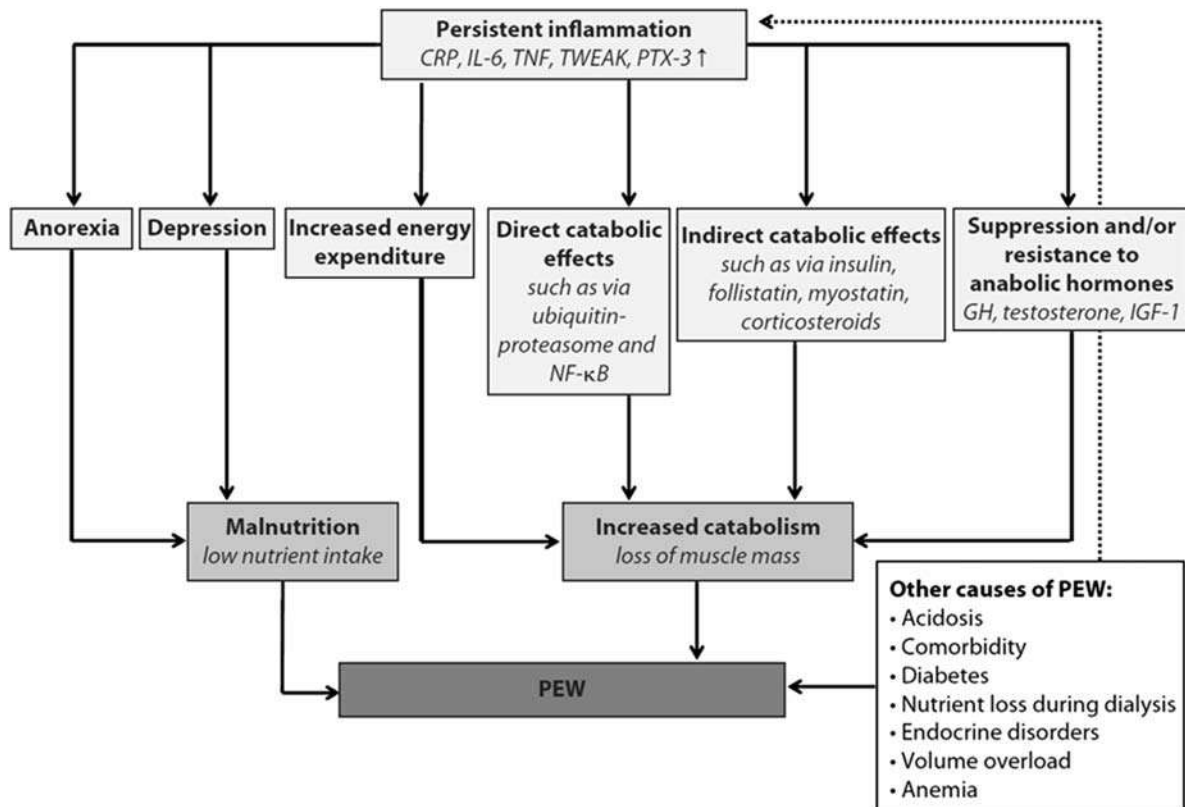

of obese sarcopenia demonstrated that PEW exists at any BMI categories (underweight, normal, and overweight), and that increased CRP or IL-6 levels were a feature of PEW in any given body weight [53]. This may be particularly true for abdominal obesity, which was accompanied by a higher prevalence of malnutrition and inflammation, while at the same time the patients have lower muscle mass and strength [45].

To finish, studies show that the inflamed uremic phenotype may also be the result of genetic differences, since Asian dialysis patients treated in the United States still have a markedly lower inflammation and lower adjusted relative risk of mortality than Caucasians [54]. Indeed, a substantial genetic heritability (35%–40%) has been found for CRP production [55,56], and many studies demonstrate a significant impact of genetic variations on the uremic inflammatory response [57,58]. Some paradoxical racial differences in CKD outcome may be, however, influenced by uremic inflammation: while in the general population, African-Americans experience a higher mortality rate than Caucasians, African-Americans treated with dialysis typically survive longer than Caucasians [59]. An American prospective cohort study of incident

dialysis patients observed that the survival advantage among African-American dialysis patients was found to only exist in the setting of high levels of inflammation [60]. Thus racial differences in the presence and response to inflammation may underlie this long-observed survival paradox and may be worthy of further investigation. Lastly and perhaps in connection to this, shortening of telomeres (nucleoprotein complexes protecting the chromosome ends that are involved in chromosome stability and repair) has been associated with an inflamed phenotype and increased mortality in dialysis patients [61].

### Inflammation as a cause of protein-energy wasting

Inflammation is an important contributory component of the complex PEW syndrome, both by direct and indirect mechanisms on muscle proteolysis, impinging upon and magnifying other causes of PEW in a vicious circle. A scheme of presentation of the mechanisms by which inflammation leads to PEW is depicted in Fig. 7.3.

**FIGURE 7.3** Proposed mechanistic pathways by which persistent inflammation may promote protein-energy wasting via malnutrition and increased catabolism in patients with CKD. CKD, Chronic kidney disease. Source: Reproduced with permission from Meuwese et al., *Contrib Nephrol* 2011;171:120–6.

## Inflammation leading to anorexia

Anorexia or loss of appetite is one of the initial steps leading to reduced nutrient intake in CKD, being this issue discussed in more detail in Chapter 38, Nutrition and Anemia in Chronic Kidney Disease. Cytokines and adipokines are capable of inducing anorexia by influencing meal size, meal duration, and frequency. Specific cytokines and adipokines also access the brain acting directly on hypothalamic neurons and/or generating mediators targeting both peripheral and/or brain target sites [62,63]. In fact, inflammation is a common feature accompanying the occurrence of anorexia in clinical studies of dialysis patients [64–67]. In addition, inflammation is also a feature of other pathophysiological processes related to the patient's ability and desire to eat, such as dental problems and incidence of periodontitis [21], alterations and infections in the gastrointestinal tract [68], and hypothalamic resistance to orexigenic adipokines [69]. Also olfactory function is impaired in patients undergoing HD and related with the severity of malnutrition and inflammation [70]. Because inflammation inhibits progenitor cell proliferation and olfactory regeneration [71], it can be speculated that persistent uremic inflammation may further impact the patient's desire to eat via this pathway.

## Inflammation and depression

Depressive symptoms are more frequent with gradual reduction in renal function and relate to poor outcome and mortality in this and other patient groups [72–74]. Cytokines are thought to be important mediators of brain immune connection and may play an important role in the pathogenesis of depression due to their effect on neurotransmitters and neurohormones [72,75]. In patients undergoing dialysis, depressive symptoms seemed to worsen in the presence of increased IL-6 levels compared to other cytokines [76–79], and 8 weeks of fluoxetine treatment in depressed HD patients decreased serum IL-1 $\beta$  levels [80]. Depression may undeniably link to fatigue [81] and unwillingness to eat [82], contributing in a vicious circle to anorexia, physical inactivity [83,84], PEW, and worse outcome, all of which have also been attributed, in part, to the effects of systemic inflammation.

## Inflammation and increased energy expenditure

Many of the metabolic abnormalities present during the inflammatory response, including fever, elevated oxygen consumption, enhanced lipolysis and fat utilization, increased concentration of catabolic hormones, and extensive protein catabolism, consume high quantities of energy and may account for as much as 15%

of the daily energy expenditure [85]. The stimulatory effect of inflammation on energy expenditure has been suggested in various studies in nondialysis and dialysis patients, in which CRP, IL-6, and physical activity levels were important determinants of energy expenditure in these populations [4,86–88]. Because increased resting energy expenditure has been associated with high mortality rates and worse nutritional status in dialysis patients [4], the impact of increased energy expenditure on muscle mass and body fat stores needs further evaluation.

## Catabolic effects of inflammation

One of the main detrimental effects of proinflammatory cytokine activation in end-stage renal disease (ESRD) patients is muscle depletion [89,90]. In animal and human studies, infusion of TNF- $\alpha$ , IL-1, and IL-6 leads to increased muscle protein breakdown [91–94]. Consequently, clinical studies in CKD patients have shown links between inflammatory cytokines and muscle wasting [3,15,95,96]. A main mechanism of inflammation-induced wasting is via the activation of NF- $\kappa$ B, ATP-ubiquitin-dependent proteolytic pathways, and caspase-3 (leading to cleavage of a characteristic 14 kDa actin fragment) that cause muscle wasting [97]. As Raj et al. [98] observed ineffective utilization of exogenous amino acids for muscle protein synthesis during HD, they hypothesized that increased skeletal muscle expression of IL-6 further augmented muscle protein catabolism in ESRD. In another study, Boivin et al. [99] reported increased caspase-3 activity (an initial step resulting in the loss of muscle protein is activated) and augmented apoptosis in uremic skeletal muscle, which may be due to increased IL-6 stimulation. TNF- $\alpha$  and IL-6 seem to play important roles in the processes of frailty and uremic wasting [15]; however, they may not explain the whole picture. Indeed, a recent study in HD patients showed that while semestral variation of IL-6 levels strongly predicted outcome, such IL-6 variation did not associate with body compositional changes in mixed multivariate models [100]. Other proinflammatory mediators that so far received relatively little attention in the nephrology community may concomitantly contribute: for instance, IL-15 is an immune-regulatory cytokine that exhibits proinflammatory activity by acting on a wide variety of cell types that, paradoxically, seem to have an anabolic role as the administration of IL-15 to cachectic tumor-bearing animals results in an improvement in the protein wasting process based mainly on the inhibition of protein degradation [101]. Recently, the TNF-related weak inducer of apoptosis (TWEAK) has been implicated in several biological responses,

including inflammation, angiogenesis, and osteoclastogenesis. As chronic administration of TWEAK resulted in reduced skeletal muscle weight in mice with an associated increase in the activity of ubiquitin–proteasome system and NF- $\kappa$ B [102], upregulation of the TWEAK-Fn14 system in the context of uremia may promote PEW [103]. Finally, Zhang et al. [94] demonstrated a previously unrecognized role of serum amyloid A in acting synergistically with IL-6 to impair insulin/insulin growth factor (IGF)-1 signaling by increasing SOCS3 transcription, which results in muscle proteolysis. They proposed that angiotensin II may stimulate an interaction between the liver and the skeletal muscle because the liver becomes the major source of both IL-6 and serum amyloid A.

### Inflammation and anabolic resistance

The uremic state is associated with abnormalities in the synthesis and action of many hormones, some of which may further contribute to the PEW syndrome, such as the case of erythropoietin and anemia. One of the most important procatabolic hormonal misbalances in CKD is insulin resistance, which in the general population has since long shown intimate links with systemic inflammation [104,105]. Administration of recombinant TNF to cultured cells or animals impairs insulin action, and obese mice lacking functional TNF or TNF receptors have improved insulin sensitivity compared with wild-type counterparts [106]. In accordance, chronic administration of infliximab (a chimeric of anti-TNF antibody) improves insulin resistance [107]. Although TNF increases lipolysis [108], which is highly linked to the development of insulin resistance, IL-6 inhibits insulin action both in vitro and in vivo muscle, liver, and adipocytes [109]. Overexpression of myostatin, a member of the transforming growth factor beta family of cytokines, may also inhibit insulin signaling as well as increase expression of FoxO [110,111]. Thus decreased insulin sensitivity caused by persistent inflammation can predispose to loss of muscle mass by decreasing the anabolic action of insulin on the skeletal muscle. In fact, in clinical conditions where insulin resistance develops, such as in elderly subjects and in patients with type-2 diabetes mellitus, muscle wasting is often observed. By using stable isotope tracer techniques, Pupim et al. [112] showed that HD patients with type-2 diabetes had significantly increased skeletal muscle protein breakdown as compared to nondiabetic HD patients. Also, incident dialysis patients with diabetes mellitus had significantly accelerated loss of lean body mass as compared to nondiabetics during the first year of dialysis therapy [113].

Resistance to anabolism by the growth hormone (GH)/IGF-1 axis may constitute another factor contributing to the loss of strength and muscle mass in CKD. While several clinical studies have reported that GH has a salutary effect on body composition and muscle protein synthesis in CKD patients [114], the responses to GH treatment vary considerably [115]. As inflammation inhibits GH action [116], it can be postulated that the GH response is blunted in uremia. Indeed, Garibotto et al. [117] found that although GH forearm perfusion caused a decrease in the negative potassium and protein balance of HD patients without inflammation, no such effect was seen in HD patients with inflammation. Their finding, thus, implies that a resistance to pharmacologic doses of GH is not related to uremia per se but rather to an increased inflammatory state. In addition, IL-6 administration inhibits IGF-1 secretion, further contributing to the sarcopenic process [118]. Interestingly, recombinant GH replacement therapy in CKD patients in well-designed studies has consistently been linked to improved anabolic function, stimulation of protein synthesis, decrease in urea generation, and improvement in nitrogen balance [119].

Low thyroid hormone levels in CKD patients have traditionally been interpreted either as an acute adaptation aimed at reducing energy expenditure and minimizing protein catabolism or as a chronic maladaptation participating in the wasting syndrome of prolonged critical illness [120]. Recent studies, nevertheless, associate low triiodothyronine levels in CKD stage 5 patients with systemic inflammatory markers (Fig. 7.4), endothelial dysfunction, and the prediction of all-cause and cardiovascular mortality [121–123]. Interestingly, correction of metabolic acidosis in dialysis patients is able to restore these hormonal derangements [124,125]. Several hypotheses connect the state of subclinical hypothyroidism with low-grade persistent inflammation in uremia [126]. Indeed, IL signaling downregulates the peripheral conversion of total thyroxine (T4) into triiodothyronine (T3) in both experimental [127] and clinical [128] studies. In HD patients, inflammation was accompanied by reductions in T3 levels, reverting these to normal as inflammation resolved [126]. It is, therefore, plausible that low T3 levels in ESKD represent an intermediate link between inflammation, PEW, and mortality. Indeed, a recent study showed in fact that the impact of free T3 on mortality prediction was abrogated after adjustment for CRP and albumin, taken in this study as surrogates of PEW [129].

Prolactin retention in CKD impairs the production of gonadotropic hormones. In men, this translates into a high prevalence of testosterone deficiency (male hypogonadism), with women displaying also very low

FIGURE 7.4 Strong inverse associations between total triiodothyronine (T3) levels and markers of inflammation (IL-6 and CRP) in euthyroid ESRD patients. CRP, C-reactive protein; ESRD, end-stage renal disease; IL, interleukin. Source: Reproduced with permission from Carrero et al., *J Intern Med* 2007;262(6):690–701.

testosterone concentrations [130–133]. Testosterone is a potent anabolic hormone that actively induces muscle protein synthesis [134]. Both muscle mass loss in wasted patients [135] and rapid weight loss during weight reduction regimens [136] have been correlated with testosterone decline. In dialysis and predialysis patients, low testosterone levels were associated with increased mortality risk [137–139], and the observation that adjustment for S-creatinine levels (used as a surrogate marker of muscle mass) abrogated this mortality prediction [137] may indirectly support this pathophysiological mechanism. Androgen therapy in uremic patients (alone or in combination with resistance training) has resulted in significant amelioration of both muscle mass and nutritional status [140,141].

### Inflammation as a catalyst for other risk factors

Persistent low-grade inflammation in CKD may, in addition to putative direct proatherogenic and proinflammatory effects, serve as a catalyst and modulate the effects of other risk factors for PEW and CVD [142]. While inflammation may enhance the appearance of PEW, inflammation can also interact with malnutrition and CVD in exacerbating the mortality risk. A Dutch study demonstrated an interaction effect between these risk factors in relation to outcome [143]. The concurrent presence of inflammation, CVD, and PEW was associated with a 16 deaths/100 person-years higher mortality rate than expected from the solo effects of these features. Thus this observation translates epidemiological observations into evidence for the existence of a syndrome of PEW, inflammation, and atherosclerotic CVD [144] where the whole is more than its parts [42]. Parekh et al. [145] also reported that while sudden cardiac death was common

among ESRD patients, inflammation and malnutrition significantly increased its occurrence independent of traditional cardiovascular risk factors. Specifically, across increasing CRP tertiles cross-classified with decreasing albumin tertiles, an exacerbation of the risk for sudden cardiac death was observed.

### Other consequences of inflammation

There is a wealth of data linking *vascular calcification* with systemic inflammation. TNF can induce mineralization of calcifying vascular cells in vitro [146] and coculture of these cells with monocyte/macrophages can accelerate mineralization [147]. Receptor activator of NF- $\kappa$ B ligand (RANKL) is a membrane-bound or soluble cytokine essential for osteoclast differentiation, whereas the decoy receptor osteoprotegerin (OPG) masks RANKL activity. As both seem to influence the inflammatory component of atherosclerosis [148], it is of interest that OPG upregulates endothelial cell adhesion molecule response to TNF [149]. These findings suggest a mechanism by which OPG may stimulate inflammation in atheroma and thereby promote the progression and complications of atherosclerosis, which would agree with the observed detrimental effects on the survival of both increased inflammation and OPG levels in HD patients [150,151]. On the other hand, vascular calcification, as part of the atherosclerotic process, is due to the deposition in the arterial intima of basic calcium phosphate crystals, similar to those that mineralize bone. It was recently shown that these crystals could interact with and activate human monocyte-derived macrophages, inducing a proinflammatory state via protein kinase C and mitogen-activated protein kinase pathways [152]. This would again imply a vicious cycle of inflammation and

arterial calcification that could explain the associations between inflammation and outcome in CKD. Finally, the most well-studied inhibitor of calcification is fetuin-A. In CKD, low levels of circulating fetuin-A are associated with cardiac valvular calcification, increased cardiovascular burden, and increased mortality risk [153–156]. Inflammation and PEW may be important causes of a decrease in serum fetuin-A levels in patients with CKD, as it behaves as a negative acute phase reactant [157,158].

The effects of inflammation may also be observed in the bone. Abnormal mineral metabolism may be both a cause and consequence of inflammation [159–161]. Increasing levels of dietary phosphate have been shown to increase TNF- $\alpha$  in a rat model of CKD [159]. Furthermore, many cytokines, including IL-6, TNF- $\alpha$ , and CRP, are associated with levels of fibroblast growth factor 23 [161] and IL-1 and IL-6 are associated with parathyroid hormone levels. High levels of TNF- $\alpha$  may stimulate RANKL and increase bone resorption through increased osteoclast activity [162] contributing to the high rates of fractures in CKD patients [163]. Finally, there is also evidence that inflammation plays a role in red blood cell formation and the development of anemia by reducing the production of erythropoietin [164], contributing to erythropoietin resistance [165], and reducing iron availability through the increased production of hepcidin [166].

### Monitoring inflammation

CRP has in the clinical setting aroused as the prototypic marker of inflammation due to its reliability, low cost, and wide availability. The key points to consider when monitoring inflammation in the clinical setting are, however, the reasons why CRP needs to be measured and the likelihood that diagnostic and therapeutic strategies might change on the basis of these test results. Despite a decade of extensive research on the causes and effects of uremic inflammation, no randomized trials with testing of inflammatory markers as the primary intervention have been performed, nor have cost-effectiveness analyses been completed to assess additional costs or cost savings through the use of such tests. Consequently, the following suggestions about the routine monitoring of inflammatory markers are not evidence-based.

### Monitoring inflammation for prognostic purposes

Prospective epidemiological studies in CKD, dialysis, or kidney transplant patients [42,167–175] have all

consistently shown that a single measurement of inflammatory biomarkers are independent predictors of poor outcomes. There is nevertheless an elevated biological intra- and interindividual variability for inflammatory mediators in the setting of CKD, even more for the unspecific CRP responses. While a decreased renal function, an increased number of comorbidities, PEW, and the uremic environment (oxidative stress, accumulation of AGEs, etc.) affect interindividual inflammatory variability [176], intraindividual variation may be further exacerbated by intercurrent clinical events, type of vascular access, membrane bioincompatibility, dialysate backflow, endotoxemia, and the intermittent presence of dialysis [40,68,177,178]. Volume status, fluid intake, and RRF are also associated with this phenomenon [179]. Although it appears essential to understand and evaluate inflammation in the context of its variability as disease evolves, few studies address the consequences of regular monitoring of inflammatory markers on outcome. Of those, it seems apparent that the average of serial measurements of CRP or IL-6 provides a better survival prediction than single measurements [68,180]. Patients with a persistent CRP or IL-6 elevation during a specific time period exhibit worse outcome than those with persistent low levels or those increasing their CRP value [1,181] (Fig. 7.5).

At present, there is insufficient evidence to support the regular monitoring of inflammation in the clinic with regards to mortality prediction. The recent study from Bazeley et al. [7] demonstrated, however, that CRP may have prognostic value beyond that provided by traditional risk factor algorithms (Framingham). The inclusion of CRP in such 1-year mortality prediction model contributed to correctly reclassify 13% of the patients with regards to their risk. Thus these results can make it possible to create specific algorithms for short-term mortality prediction in CKD patients. Whether this may have prognostic applicability is not yet evident, but such algorithm could represent a decision tool toward the implementation of more aggressive therapeutic approaches in dialysis patients at risk.

### Monitoring inflammation for diagnostic purposes

Probably the most useful indication of CRP monitoring is the screening and detection of underlying inflammatory processes and the assignment of appropriate treatment [182]. Possible underlying inflammatory processes include graft- or catheter-related infections, peripheral arterial disease, silent coronary ischemia, ulcers, inflammatory bowel disease, malignancies, periodontitis, or hepatitis. According to

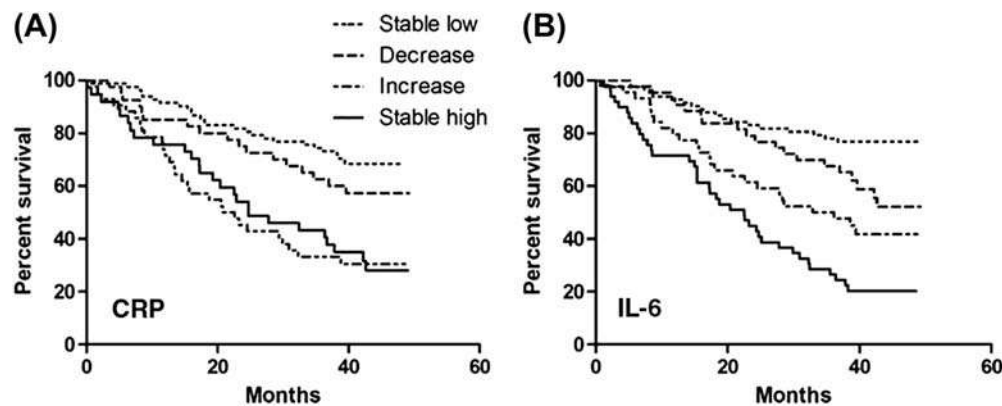

FIGURE 7.5 Persistent elevation of (A) CRP and (B) IL-6 in hemodialysis patients during a 3-month monitoring was associated with increased risk of mortality. CRP, C-reactive protein; IL, interleukin. Source: Reproduced with permission from Meuwese et al., *Nephrol Dial Transplant* 2011;26(4):1313–8.

AHA/CDC recommendations, a second CRP measurement taken 2 weeks after the first might be useful in identifying transient processes while reducing biological variation in usual clinical practice. A careful patient monitoring is warranted as well after these processes are resolved, as it has been reported that during the 30 days following an infection-related hospitalization in dialysis patients, the risk of cardiovascular events increases by 25% [183]. Patients showing CRP elevations over short periods of time should undergo an extensive clinical workup, whether they exert clinical symptoms or not. Other seemingly valid reasons for performing serial CRP measurements could be to motivate individuals at risk of inflammation to improve their lifestyles (such as smoking cessation, dental care, dietary modification, exercise, and weight loss) or to comply with drug therapies. Clearly, persistent CRP elevations or increases in inflammatory biomarkers indicate patients at high risk of dying, and major efforts should be made to address the causes of such elevations.

### Treatment of inflammation in chronic kidney disease

Few randomized controlled trials have been successful in managing inflammation in patients with CKD and no sufficiently powered randomized controlled trials targeting uremic inflammation as a means of improving morbidity and mortality in CKD patients have yet been performed. Nor is there evidence that by improving systemic inflammation, nutritional status is restored. Therefore the following recommendations for treating inflammation in patients with CKD reflect the authors' opinion. Based on the concept that inflammation plays a pivotal role in the development of the

uremic phenotype, circulating inflammatory markers have the potential to be primary targets for novel treatments, including not only specific antiinflammatory therapies but also various antioxidative and antiwasting approaches.

When preexisting complications (including dialysis-related causes and smoking) have been excluded as a cause of persistent inflammation, some interventional approaches could be cautiously considered, including strategies to modify physical activity [184,185], cognitive behavior [186], and modifying the diet [187,188], including the use of bioactive nutrients with immune properties [189–194].

Certain medications have nonspecific immunomodulatory effects on CKD. For instance, in inflamed patients with moderate CKD, rosuvastatin treatment reduced CRP levels and improved both cardiovascular events and all-cause mortality [195]. In contrast, data on the effects of statins on inflammatory biomarkers in ESKD are not that consistent [196,197]. Cholecalciferol supplementation may also have antiinflammatory properties in CKD patients [198,199]. Sevelamer, which possesses AGE- and lipopolysaccharide-binding properties, is associated with a reduction in circulating CRP and endotoxin levels as well as amelioration of endothelial dysfunction [200–202]. Angiotensin converting enzyme inhibitors/angiotensin receptor blocker [203–205], aliskiren (a direct renin inhibitor) [206], or allopurinol [207] have also shown suppressive effects on inflammatory markers. Among the currently available anticytokine therapies, etanercept, a TNF-receptor antagonist, was tested targeting uremic persistent inflammation in a small number of patients on HD, primarily aiming at an improvement in nutritional profiles [208]. Forty-four weeks of treatment with etanercept showed positive effects on albumin and prealbumin levels compared to the placebo group with no occurrence of adverse events, while the treatment

resulted in a nonsignificant change in CRP and IL-6 [208]. Anakinra, a recombinant human IL-1-receptor antagonist, lowered plasma CRP and IL-6 levels in patients with type-2 diabetes [209]. In a recent small prospective controlled trial [210], 22 patients with markers of inflammation on HD were randomized to anakinra or placebo over 4 weeks. As those who received treatment showed a 53% reduction in CRP, 40% reduction in IL-6 levels, and 23% increase in mean prealbumin, further studies are needed to evaluate the impact of such therapy on outcome in this patient group. Finally, it should be recognized that persistent inflammation might impact on drug metabolism as inflammation is able to downregulate multiple P450 enzymes [211]. Indeed, a study showed a strong correlation between CRP levels and CYP3A4 activity (assessed by alprazolam 4-hydroxylation) in a small group of HD patients [212]. How this may affect the metabolism of commonly used drugs in CKD deserves further study.

# Catalytic (labile) iron in kidney disease

Sundararaman Swaminathan<sup>1</sup> and Sudhir V. Shah<sup>2</sup>

<sup>1</sup>Division of Nephrology and Hypertension, Mayo Clinic Arizona, Scottsdale, AZ, United States <sup>2</sup>Division of Nephrology, Department of Internal Medicine, UAMS College of Medicine, Little Rock, AR, United States

## Introduction

Despite advances in understanding the pathophysiology of acute kidney injury (AKI) and chronic kidney disease (CKD), treatment for kidney disease remains unsatisfactory. In this chapter, we briefly recount the importance of AKI and CKD, then provide a brief description of labile iron, and, finally, summarize the role of labile iron in acute and CKD. This focus on iron is particularly relevant because of the availability of iron chelators to potentially provide new therapeutic tools to prevent and/or treat kidney disease.

Several recent studies highlight the clinical relevance of AKI. AKI has been shown to be an independent risk factor for morbidity and mortality, and even a modest increase in serum creatinine (0.3 mg/dL) is associated with high in-hospital mortality [1]. Recent studies indicate that AKI is an important determinant of posthospital discharge mortality [2,3] as well as end-stage kidney disease (ESKD) [4,5]. The suggested new definition of AKI and the rationale behind it is detailed in the publication [6] resulting from a consensus conference under the auspices of the Acute Kidney Injury Network, in which over 20 global societies representing both nephrologists and intensive care physicians participated.

CKD is a global public health problem that affects approximately 10%–15% of the adult population [7,8] and is associated with a high prevalence of cardiovascular disease [9] and high economic cost [10]. The expected marked increase in diabetes, the most common cause of CKD; increasing incidence of ESKD despite the use of angiotensin receptor blockers (ARBs); and the multiplier effect of CKD on cardiovascular disease, all point to a major challenge facing health-care systems worldwide. Despite promising results [11], a phase 3 trial for a novel treatment for

diabetic nephropathy was unsuccessful [12]. While there are promising new therapeutic approaches, such as sodium–glucose-co-transporter-2 inhibitors to retard progression of diabetic CKD and reduce cardiovascular mortality [13], there is continued urgent need for new therapeutic modalities for halting progression of kidney disease.

## Definition of catalytic (labile) iron and its importance in tissue injury

Iron is the most abundant transitional metal in the body (Table 8.1). The term “labile iron pool” was proposed in 1946 by Greenberg and Wintrobe [14] and reintroduced by Jacobs in 1977 as a “transient iron pool” to denote a low-molecular-weight pool of weakly chelated iron that passes through the cell. The term “chelatable iron” is also used, as most methodological approaches for detection of this pool of iron ions are based on the use of metal chelators [15]. Critical to iron’s importance in biological processes is its ability to cycle reversibly between its ferrous and ferric oxidation states. This precise property, which is essential for its functions, also makes it very dangerous, because free iron can catalyze the formation of free radicals that can damage the cell through lipid peroxidation. *Thus from a pathophysiological standpoint, the broadest definition of a labile iron pool is that it consists of chemical forms that can participate in redox cycling and is therefore often referred to as catalytic iron* [16].

Our bodies contain as much as 3–5 g of total iron, but the pool of labile iron that can be measured [16,17] is estimated to be less than 70–90 mg. Although the existence of a cellular pool of metabolically labile iron proved controversial, the development of iron-sensitive fluorescent probes has provided much evidence in favor

TABLE 8.1 Catalytic (labile) iron.

What is catalytic iron?

LIP, Labile iron pool.

of intracellular labile pools [18]. In most cells iron homeostasis consists of iron uptake, utilization, and storage. The process of iron uptake is carried out by a transferrin receptor and the divalent metal transporter 1 (also called DCT1; NRAMP2), whereas ferritin is an intracellular iron-sequestering protein. Recent studies are beginning to yield information on the pathways of iron transport, its export from the cell via the divalent iron ion exporter ferroportin 1 [19] and its regulatory mechanisms by hepcidin, the master regulator of iron homeostasis [20]. Since uptake and storage of iron is carried out by different proteins, the pool of accessible iron ions constitutes a crossroad of metabolic pathways of iron-containing compounds.

Probes for labile iron are comprised of a fluorescent reporter group coupled to a high-affinity iron (II or III) chelator. The fluorophore responds to metal binding by undergoing a change in fluorescence. The most commonly used fluorophores include fluorescein and rhodamine derivatives attached to a chelator (reviewed in Ref. [21]). A complementary approach for estimating cellular labile iron is based on metal-driven catalysis of oxidant formation [22]. The advantages of this method are high sensitivity and selectivity for redox-active labile iron. Studies using a variety of methods have begun to define intracellular distribution of labile iron (for reviews see Kruszewski [15] and Esposito [21]).

In vivo, most of the iron is bound to heme or non-heme protein and does not directly catalyze the generation of hydroxyl radicals or a similar oxidant [15]. Catalytic iron can be measured by various assays, including the bleomycin-detectable iron assay, which is based on the observation that the antitumor antibiotic bleomycin, in the presence of iron salt and a suitable reducing agent, binds to and degrades DNA with the formation of a product that reacts with thiobarbituric acid to form a chromogen. Thus the assay detects iron complexes capable of catalyzing free-radical reactions in biological samples [23,24]. The binding of the bleomycin–iron complex

to DNA makes the reaction site-specific and antioxidants rarely interfere. The bleomycin assay detects only “free” iron and not iron bound to specific transport proteins or enzymes. The ability of iron to participate in redox cycling makes it potentially hazardous by enabling it to participate in the generation of powerful oxidant species such as hydroxyl radical (metal-catalyzed Haber–Weiss reaction, next) and/or reactive iron–oxygen complexes such as ferryl or perferryl ion [16]. In several systems the amount of free-radical generation is related to the amount of labile iron present [17].

Iron also has a major role in the initiation and propagation of lipid peroxidation, either by catalyzing the conversion of primary oxygen radicals to hydroxyl radicals or forming a perferryl ion. In addition, iron can directly catalyze lipid peroxidation, the oxidative reaction of polyunsaturated lipids, by removing hydrogen atoms from polyunsaturated fatty acids in the lipid bilayers of organelle membranes [16]. Lipid peroxidation products, such as doubly or triply oxidized phosphatidylethanolamine (PE), have been identified to be the key executors of iron-induced cell death, also called ferroptosis. Generic or pharmacological suppression of acyls-arachidonoyl and adrenoyl esterification into PE through inhibition of acyl-CoA synthase 4 acts as a specific ferroptosis rescue pathway. Lipoxxygenase (LOX-5 and LOX-15) generates doubly and triply oxygenated (15-hydroperoxy)-diacylated PE species, which also act as ferroptotic death signals; tocopherols and tocotrienols (vitamin E) that suppress LOX protect against ferroptosis, suggesting a homeostatic anti-ferroptosis role for vitamin E [25].

The pathological effects of iron accumulation in tissue in iron-overload states, such as are described in thalassemia patients, are well known. What is new in the field is the recognition that iron plays an important role in the pathophysiology of tissue injury in the absence of systemic iron overload. There appear at least two distinct pathophysiological mechanisms for the accumulation of labile or catalytic iron that participate in tissue injury. It is now known that specific defects in cellular iron metabolism and/or an increase in labile iron may be important in several disease processes not associated with iron overload [18,26]. For example, in Friedreich's ataxia, a neuromuscular disorder, the deficiency of the iron-chaperone protein fra-taxin results in improper processing of iron for heme and iron-sulfur cluster formation, leading to accumulation of iron in the mitochondria [27]. In some other neuromuscular disorders, deficiencies in pantothenate kinase, a key enzyme in coenzyme A synthesis, lead to iron depositions and brain damage [26]. In addition to these specific defects in cellular iron, there is compelling evidence that increased labile iron from several subcellular sources participates in tissue injury in a variety of disease states.

There are two broad lines of evidence for the role of labile iron in disease states: that it is increased in disease states and that iron chelators provide a protective effect, thus establishing a cause-effect relationship (Table 8.1). This has been demonstrated in many disease states, including acute and CKD, acute myocardial infarction, and neurodegenerative disorders [27]. Thus its role in disease processes appears to be a common theme of cellular injury.

## Role of catalytic iron in acute kidney injury

### **Catalytic iron in myoglobinuric acute kidney injury**

During the Battle of Britain, Bywaters and Beall described the first causative association of AKI with skeletal muscle injury with release of muscle cell contents, including myoglobin, into plasma (rhabdomyolysis) [28]. Since then, the spectrum of etiologies for rhabdomyolysis, myoglobinuria, and renal failure has been expanded with the recognition of both traumatic and nontraumatic causes [29]. The most widely used model of myoglobinuric AKI is produced by subcutaneous or intramuscular injection of hypertonic glycerol [30].

There is a marked and specific increase in catalytic iron content in myoglobinuric AKI [31]. An iron chelator provides a protective effect on renal function and is associated with a significant reduction in histological evidence of renal damage [32]. Paller also demonstrated that deferoxamine

treatment is protective in three models of myoglobinuric renal injury, hemoglobin-induced nephrotoxicity, glycerol-induced AKI, and a combined renal ischemia/hemoglobin insult [33]. Similarly, Zager in his studies demonstrated the protective effect of an iron chelator in myohemoglobinuric injury [34]. Taken together, the increase in catalytic iron as well as the histological and functional protective effect of an iron chelator implicates a role for labile iron in glycerol-induced AKI.

The prevailing dogma is that myoglobin from the muscle serves as an important source of iron in glycerol-induced AKI. This is not surprising because myoglobin released from injured muscles is rich in heme iron. An alternative or additional potentially rich source of iron is cytochrome P450 (CYP), first described to play a role in reperfusion injury of the lung and kidney [35]. Cytochrome P450 is a heme-containing enzyme that can generate reactive oxygen metabolites during the oxidative metabolism of exogenous and endogenous compounds. Baliga et al. have shown that cytochrome P450 may be a significant source of iron in this model of AKI [31]. H-ferritin is a critical molecule that sequesters intracellular iron. In a recent study, deletion of H-ferritin in renal proximal tubule resulted in worse rhabdomyolysis-associated kidney injury, further suggesting an important role iron in AKI [36].

### **Catalytic iron in cisplatin-induced nephrotoxicity**

Cisplatin is a widely used antineoplastic agent with nephrotoxicity as a major side effect. The underlying mechanism of this nephrotoxicity is still not well known. Baliga et al. have examined the catalytic iron content and the effect of iron chelators in an in vitro model of cisplatin-induced cytotoxicity in LLC-PK<sub>1</sub> (renal tubular epithelial) cells and in an in vivo model of cisplatin-induced AKI in rats [37]. The exposure of LLC-PK<sub>1</sub> cells to cisplatin results in a significant increase in catalytic iron released into the medium. Concurrent incubation of LLC-PK<sub>1</sub> cells with iron chelators, including deferoxamine and 1,10-phenanthroline, significantly attenuates cisplatin-induced cytotoxicity as measured by lactate dehydrogenase release. Bleomycin-detectable iron content is also markedly increased in the kidney of rats treated with cisplatin. Similarly, administration of deferoxamine in rats provides marked functional (as measured by blood urea nitrogen and creatinine) and histological protection against cisplatin-induced AKI [37]. Further support comes from the observation that deletion of H-ferritin in renal proximal tubule resulted in worse cisplatin-induced kidney injury [36].

Baliga et al. also have shown that cytochrome P450 may serve as a significant source of catalytic iron in cisplatin-induced nephrotoxicity [38]. Utilizing CYP2E1null (CYP2E1<sup>-/-</sup>) mice, Liu and Baliga

have demonstrated a pivotal role of CYP2E1 in cisplatin-induced nephrotoxicity [39]. Incubation of CYP2E1<sup>-/-</sup> kidney slices with cisplatin results in a significant decrease in the generation of reactive oxygen metabolites and attenuation of cytotoxicity as compared to that of wild-type mice (CYP2E1<sup>+/+</sup>). CYP2E1null mice had marked functional and histological protection against cisplatin-induced renal injury, thus demonstrating the importance of cytochrome P450 2E1 in cisplatin nephrotoxicity. More recently, studies have confirmed the ability of cisplatin to induce ferroptosis [40]. Taken together, these data support a critical role for iron in mediating tissue injury via hydroxyl radical (or a similar oxidant) in this model of nephrotoxicity.

### Catalytic iron in gentamicin nephrotoxicity

Nephrotoxicity is a major complication of the use of aminoglycoside antibiotics (including gentamicin), which are widely used in the treatment of Gram-negative infections. The precise mechanism(s) of gentamicin nephrotoxicity remains unknown.

#### Gentamicin-induced mobilization of iron from renal cortical mitochondria

In vivo, most of the iron is bound to heme and non-heme proteins and does not directly catalyze the generation of the hydroxyl radical; the source of iron available to participate in this process is uncertain. Based on the ability of superoxide to release iron from the iron-storage protein ferritin (which normally provides a secure means of storing iron in an inert form), ferritin has been suggested as a possible source of iron for the generation of powerful oxidant species. A source of iron not previously considered is iron-rich mitochondria, which contain heme as well as nonheme iron.

Ueda et al. examined whether gentamicin enhances the release of iron from renal cortical mitochondria and, if so, whether gentamicin induces iron mobilization from mitochondria directly or through the generation of hydrogen peroxide [41]. Rat renal mitochondria incubated with gentamicin results in a time- and dose-dependent iron release as measured by the formation of the iron–bathophenanthroline complex FeII(BPS)<sub>3</sub>. Based on a previous study that gentamicin enhances the generation of hydrogen peroxide by renal cortical mitochondria, Ueda et al. examined whether the effect of gentamicin on iron release is mediated by hydrogen peroxide. Catalase (which decomposes hydrogen peroxide), as well as pyruvate, a potent scavenger of

hydrogen peroxide, prevents gentamicin-induced iron mobilization, indicating that gentamicin-induced iron mobilization from mitochondria is mediated by hydrogen peroxide. Direct addition of hydrogen peroxide to mitochondria results in release of iron. These results demonstrate that gentamicin induces the release of iron from mitochondria and that this is mediated through the generation of hydrogen peroxide. In recent studies, aminoglycoside-induced bacterial cell death was shown to depend on destabilization of mitochondrial iron–sulfur (Fe–S) clusters generating Fenton chemistry [42,43]. A similar oxidative mechanism might operate in aminoglycoside-induced renal- and ototoxicity. These results indicate that mitochondria should be considered a potential source of iron for the generation of other oxidant species or initiation of lipid peroxidation in other models of tissue injury.

#### Evidence suggesting a role for iron in gentamicin-induced acute renal failure in rats

In vitro and in vivo studies indicate enhanced the generation of hydrogen peroxide and release of iron in response to gentamicin. Most, if not all, of the hydrogen peroxide generated by mitochondria is derived from the dismutation of superoxide. Thus the enhanced the generation of hydrogen peroxide by gentamicin suggests that superoxide anion production is also increased. Superoxide and hydrogen peroxide may interact (with trace metals such as iron as the redox agent) to generate highly reactive and unstable oxidizing species, including the hydroxyl radical. Several studies have in fact shown that agents that enhance the generation of hydrogen peroxide and superoxide anion by mitochondria also enhance the generation of the hydroxyl radical. Walker and Shah demonstrated that hydroxyl radical scavengers and iron chelators provide a marked protective effect on renal function in gentamicin-induced acute renal failure in rats [44]. In addition, histological evidence of damage is markedly reduced by the interventional agents. Studies from other laboratories have provided support for these observations. Administration of superoxide dismutase or the oxidant scavenger dimethylthiourea provided a marked protection against gentamicin-induced impairment of renal function and lipid peroxidation, and dimethylthiourea attenuated tubular damage [45]. In contrast, it has been reported that, despite amelioration of gentamicin-induced lipid peroxidation by treatment of the antioxidant diphenylphenylenediamine, it failed to prevent nephrotoxicity [46]. However, it was also demonstrated that coadministration of antioxidants vitamin E and selenium is protective against gentamicin-induced nephrotoxicity [47]. It is not clear why the contradictory results are obtained; however, one explanation is that it may be due to the difference in the

mechanisms for protective effect of antioxidants. Additional support for a role of iron-catalyzed free-radical generation has been provided by demonstrating that gentamicin-induced the generation of hydroxyl radicals is reduced by iron chelators in vitro [48] and iron supplementation enhances gentamicin nephrotoxicity in vivo [49,50]. Iron depletion might mediate protection through its ability to reduce the activity of the iron–sulfur cluster containing complexes [51] and thereby Fenton chemistry. Taken together, it appears that reactive oxygen metabolites and catalytic iron play an important role in gentamicin nephrotoxicity.

### Catalytic iron in contrast media–associated nephrotoxicity

Rajapurkar et al. in a preliminary study have reported that kidney donors undergoing either an intravenous pyelogram or a renal arteriogram have a marked increase in urinary catalytic iron accompanied by evidence of tubular injury as reflected by an increase in urinary alkaline phosphatase and *N*-acetyl- $\beta$ -glucosaminidase [52]. Since the effect of labile iron is to increase oxidative stress, it is of interest that there is good experimental evidence for the role of oxidants in contrast-induced AKI [53–55]. More importantly, in human studies, Efrati et al. reported a mean increase of 28% in urinary F2-isoprostane levels after coronary angiography [56]. Drager et al. collected urine samples for urinary F2-isoprostane (a marker of oxidative stress) immediately before and after cardiac catheterization and reported a several-fold increase in urinary F2-isoprostane in the control group after contrast exposure [57].

While these human studies indicate an association between catalytic iron and oxidative stress with contrast-induced nephropathy, they do not establish a cause–effect relationship. There is paucity of animal models of contrast-induced AKI [58]. Vari et al., utilizing a model in rabbits that they have developed [59], examined the effect of an iron chelator on renal function. An infusion of contrast media was associated with a significant decrease in creatinine clearance, which was prevented in rabbits pretreated with an iron chelator, suggesting an important role of catalytic iron in this model (Table 8.2) [60]. In a recently established murine model, volume depletion alone resulted

in a rise in the serum creatinine level, in wild-type mice; iodinated contrast (Ioversol)–induced further worsening of AKI with a greater increase in serum creatinine at 72 hours. In this study, renal infiltration of macrophages, activation of inflammasomes, and interleukin-1 were shown to be critical for contrast-induced AKI [61]. Iron chelation with deferiprone has been shown to target macrophage metabolism to reduce inflammatory responses, including interleukin-1 release [62]. Collectively, these studies indicate a macrophage-dependent antiinflammatory mechanism for the protective effect of iron chelation in contrast-induced AKI.

### Catalytic iron in ischemia–reperfusion injury

Ischemia–reperfusion is an important cause of AKI. In this section, evidence for the role of labile iron in this injury is reviewed. In addition, we briefly describe the role of labile iron in cardiac ischemia–reperfusion injury to provide supportive evidence for these mechanisms in cellular injury.

Iron has been demonstrated to accumulate in renal proximal tubules following experimental ischemia–reperfusion injury [63]. More importantly, Baliga et al. have shown a marked increase in labile iron after ischemia–reperfusion injury [64], and an iron chelator has been shown to be protective [65,66]. Additional evidence for the role of iron in ischemia–reperfusion injury comes from reports that other types of iron-binding and/or iron-translocating compounds also provide protection against ischemia. The amount of circulating redox-active iron has been shown to increase significantly in an experimental model of ischemia–reperfusion injury, and an infusion of apotransferrin (but not iron-saturated apotransferrin) results in a dose-dependent improvement in renal function following reperfusion [67]. In addition, the recent discovery of neutrophil gelatinase–associated lipocalin (NGAL), which is an important iron-transporting and iron-translocating compound, provides additional evidence for the importance of iron in AKI [68]. The biology of NGAL is complex and incompletely defined, but it is important in renal development in that it stimulates the epithelial cell phenotype, is proapoptotic, and is an iron-binding and iron-transporting protein [69]. Furthermore, NGAL is one of the most upregulated genes and proteins in the kidney following ischemic insult [68], and infusion of NGAL protein has been demonstrated to be protective of renal ischemia–reperfusion injury [69].

During experimental cardiac ischemic injury, there is a 30-fold increase in labile iron [70]. This increase in the cellular labile iron pool is mediated primarily by

TABLE 8.2 Animal model of contrast-induced nephropathy.

the release of iron from ferritin and is associated with severe oxidative stress, which in turn further increases levels of cellular labile iron [70–72]. Therapeutically, both deferiprone and deferoxamine have been demonstrated to protect against experimental cardiac ischemia–reperfusion injury [73–75]. Iron loading has been demonstrated to further increase cardiac ischemia–reperfusion injury and again deferoxamine is protective, even in the iron-overloaded state [73]. Hepcidin is a master regulator of iron homeostasis through its ability to downregulate ferroportin and thereby induce H-ferritin-dependent intracellular iron sequestration. Scindia et al. demonstrated that preadministration of hepcidin induced hepatosplenic iron sequestration, increased splenic and renal H-ferritin expression, and prevented renal ischemia–reperfusion injury in mice [76]. In a recent study, Leaf et al. demonstrated that plasma catalytic iron levels predict the risk of AKI and mortality after cardiac surgery [77]. Further, deferoxamine has also been shown to improve outcomes in man following coronary artery bypass graft surgery [78]. Taken together, the body of scientific and clinical data supporting the importance of the role of iron in the pathogenesis of ischemic injury is compelling. The role of catalytic iron and oxidants in AKI is summarized in Table 8.3.

### Catalytic iron in chronic kidney disease

#### Catalytic iron in experimental glomerular disease

The role of iron has been examined in several models of leukocyte-dependent and -independent models of glomerular disease [79] (Table 8.3). The antiglomerular basement membrane antibody is a well-characterized model of complement- and neutrophil-dependent glomerular injury. In this model in rabbits, Boyce et al. reported that an iron chelator significantly attenuates proteinuria [80]. In addition to proliferative glomerulonephritis, the ability of glomerular cells to generate oxidants suggests that they may act as important mediators of injury in glomerular diseases that lack infiltrating leukocytes. An animal model

of minimal change disease is induced by a single intravenous injection of puromycin amino nucleoside. Catalytic iron (measured as bleomycin-detectable iron) is markedly increased in glomeruli from nephrotic rats, and an iron chelator prevents an increase in catalytic iron in the glomeruli and provides complete protection against proteinuria, suggesting an important pathogenic role for catalytic iron in this model [81,82].

Baliga et al. have demonstrated that cytochrome treatment of PAN resulted in a marked increase in catalytic iron associated with significant loss of glomerular cytochrome P450 content. Administration of CYP inhibitors significantly prevented injury-induced loss of CYP content and increase in catalytic iron in the glomeruli accompanied by a marked decrease in proteinuria [83]. In an in vitro study using glomerular epithelial cells, CYP inhibitors also markedly prevented a PAN-induced increase in catalytic iron and hydroxyl radical formation accompanied by significant protection against PAN-induced cytotoxicity. Taken together, these data indicate that CYP, a group of heme protein, may serve as a significant source of this catalytic iron. In addition, they have shown with in vivo and in vitro studies that cytochrome P450 2B1, an isozyme present in the glomerulus, is a source of catalytic iron that participates in glomerular injury in this model [84,85].

Passive Heymann nephritis, induced by a single intravenous injection of anti-Fx1A, is a complement-dependent model of glomerular disease that resembles membranous nephropathy in humans. The administration of an iron chelator markedly reduces proteinuria, suggesting the role of labile iron in passive Heymann nephritis [86]. Baliga et al. have shown that feeding an iron-deficient diet provides the protection in this model [87].

#### Role of iron in experimental progressive kidney disease

The severity of tubulointerstitial injury is a major determinant of the degree and rate of progression of renal failure. The data supporting the role of iron in models of progressive renal disease consist of demonstration of increased iron in the kidney; enhanced oxidant generation, which provides a mechanism by which iron can be mobilized; and the beneficial effect of iron-deficient diets and iron chelators. Rats with proteinuria have increased iron content in proximal tubular cells, and iron accumulation was the only independent predictor of both functional and structural damage [88]. Similarly, it has been shown that there is a substantial iron accumulation associated with increased cortical malondialdehyde in proximal tubular cells in the remnant kidney,

suggesting reactive oxygen species generation. The sources of increased iron in the kidney have not been well delineated, but Alfrey et al. have suggested that urinary transferrin provides a potential source of iron [89,90].

Several studies have demonstrated an important role of iron in progressive kidney disease. It was reported that an iron-deficient diet (Fig. 8.1) or iron chelators prevent the development of tubulointerstitial disease and renal functional deterioration in nephrotoxic serum nephritis [90,91]. Remuzzi et al. have shown that rats fed an iron-deficient diet have a significant reduction in proteinuria and develop less glomerulosclerosis [92]. An iron chelator significantly reduces iron accumulation and tubular damage in the rat remnant kidney, a model for progressive renal disease [93].

### Catalytic iron in human disease

A sufficient body of in vitro and in vivo information exists to postulate that catalytic iron is an important mediator in glomerular pathophysiology and progressive kidney disease. While the collective information on the role of oxidants and iron derived from models of glomerular disease as well as progressive renal failure is impressive, there is little information on the potential role of these mechanisms in human disease. There are many differences between animal models and glomerular disease in humans. For example, the animal model of minimal change disease is a toxic model, whereas the mechanism of minimal change disease in humans is not known. Similarly, the anti-Fx1A antibody, which is used for the animal model of membranous nephropathy, has been difficult to demonstrate in human membranous nephropathy. Indeed, the lessons from animal models of AKI have been disappointing when attempting to translate to human disease. We will summarize the limited information from human studies, which lend support that the mechanisms

observed in animal models appear to be applicable to human disease.

### Catalytic iron in diabetic nephropathy

Howard et al. have shown that urinary iron excretion is increased early in the course of diabetic kidney disease in humans [94]. We have compared labile iron in subjects with no renal disease or diabetes to patients with diabetes (Fig. 8.2A). Our data demonstrate that patients with overt diabetes have a marked increase in urinary catalytic iron. Similarly, patients with microalbuminuria have a marked and highly significant increase in urinary catalytic iron, indicating that urinary catalytic iron is not merely a reflection of albuminuria. Finally, some patients in the diabetic control group who do not have microalbuminuria have high catalytic iron, leading us to postulate that urinary catalytic iron precedes the onset of microalbuminuria and may predict patients at risk for diabetic nephropathy. Interestingly, recent studies have demonstrated that nontransferrin-bound iron levels are frequently increased in diabetes and have been implicated in a few studies with the vascular complications of diabetes [95].

We conducted a single-center, single-arm, open-label, proof-of-concept study to evaluate the safety and efficacy of the oral iron chelator deferiprone in reducing albuminuria in patients with diabetic nephropathy [96]. Adult patients with a diagnosis of diabetes mellitus and significant abnormal albumin excretion but with serum creatinine levels  $<1.2$  mg/dL were included in this study. Patients received standard of care and enalapril, which was kept constant throughout the study. Deferiprone was administered in a daily dose of approximately 50 mg/kg in three divided doses for 9 months. The mean age of the 37 patients (21 males and 16 females) was  $51.27 (\pm 1.67)$  years. The blood glucose control measured by HbA1c was not significantly different between the baseline and final visit ( $P = .68$ ). The mean albumin-to-creatinine ratio decreased with treatment of deferiprone as shown in

FIGURE 8.1 Effect of a low-iron diet in halting progression of kidney disease. Feeding a low-fat diet to rats with nephrotoxic serum nephritis prevented a rise in serum creatinine (vertical axis) over time course in days (horizontal axis) and provided histological protection (data not shown).

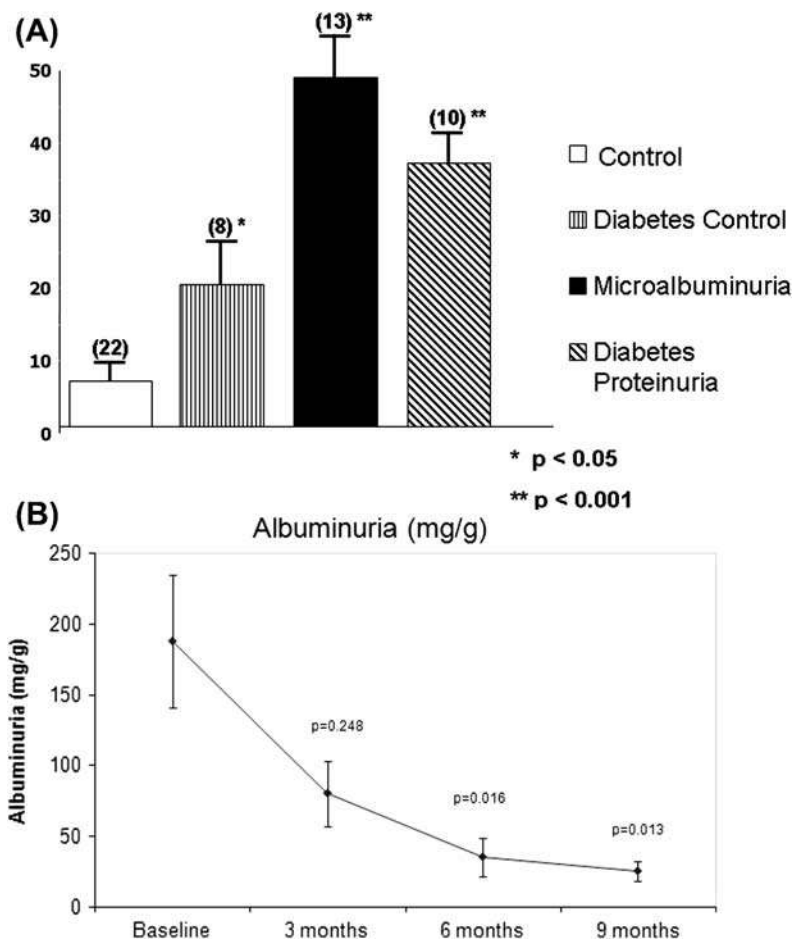

FIGURE 8.2 Urinary catalytic iron (nmols/L) in patients with diabetic nephropathy (A) and the effect of the iron chelator deferiprone on proteinuria (B).

Fig. 8.2B. The serum creatinine levels remained stable throughout the course of the study. The calculated mean arterial blood pressure declined from a baseline value of  $100.78 \pm 1.7$  to  $97 \pm 0.6$  at 3 months ( $P = .2$ ) but remained relatively stable from then on to 6 months ( $96.24 \pm 0.7$ ;  $P = .6$ ) and 9 months. No clinically significant side effects were observed. Future randomized, double-blind trials, with careful monitoring of safety issues, may lead to the use of a new class of agents for the treatment of diabetic nephropathy.

### Catalytic iron in chronic kidney disease

Nankivell et al. have reported increased iron content in patients with CKD [97]. Using the urinary catalytic iron assay described previously, we have shown a marked increase in patients who have biopsy-proven glomerulonephritis (Fig. 8.3A).

We conducted an open-label, proof-of-concept study in which patients with biopsy-proven glomerulonephritis were treated with deferiprone (50 mg/kg/day), and protein and serum creatinine were obtained

2–6 months after the administration of the iron chelator. As shown in Fig. 8.3B–D, treatment with the iron chelator significantly decreased the amount of total urinary protein in patients with glomerulonephritis [98]. Serum creatinine was  $1.10 \pm 0.15$  before and  $0.90 \pm 0.10$  ( $n = 11$ ) at the end of the study period. Our data indicate an increase of catalytic iron in patients with glomerulonephritis and that treatment with an oral iron chelator leads to a reduction in proteinuria.

There is at least one published study in the literature in which the effect of a metal chelator on progressive kidney disease has been examined. Lin et al. have shown that chelation therapy with ethylenediaminetetraacetic acid (EDTA) in patients with chronic renal insufficiency results in a reduced rate of decline in the glomerular filtration rate (GFR) [99]. The authors attribute the beneficial effect to the chelation of lead, which also participates in the Fenton reaction. However, given the affinity constants for iron and lead, the large experimental evidence for the role of iron in kidney disease, and the demonstrated efficacy of EDTA in enhancing excretion of urinary iron, we believe that the beneficial effects are more likely to be explained by the chelation of iron rather than lead [100].

### Concluding comments

One has to be cautious in extrapolating results from animal studies to humans. Unfortunately, all clinical trials in AKI based on animal models have failed. These include trials related to atrial natriuretic peptide [101,102], insulin-like growth factor [103,104], thyroxine [105,106], and furosemide [107,108]. Nonetheless, evidence that labile iron appears to be involved in a variety of models of AKI suggests that it may be a common mechanism of tissue injury. Additionally, the demonstration of an increase in labile iron in humans lends support to the possibility of similar pathophysiological mechanisms in humans. The availability of iron chelators with a favorable side-effect profile for short-term use makes them attractive for randomized clinical trials to evaluate their efficacy and safety in preventing or treating AKI.

There are several points from animal and human studies related to halting progression with a metal chelator that are worth noting. The observation that a reduction in

proteinuria (provided it is not attributable to a fall in GFR) results in slowing progression of kidney disease has been reasonably well established, but only with ACE inhibitors and ARBs. This is in keeping with the data that albumin itself appears to have a significant effect on tubular cells, including enhanced the generation of oxidants and activation of the inflammatory response. However, it is conceivable for a therapeutic agent to preserve the tubulointerstitial region by abolishing the consequences of proteinuria or having a direct protective effect on the tubules. In diabetic and nondiabetic CKD, animal and human studies highlight the possibility of a beneficial effect without a reduction in proteinuria. A recent study demonstrated that bicarbonate supplementation slowed the rate of progression of renal failure to ESRD without reducing proteinuria [109]. In an open-label trial, pirfenidone was shown to slow the loss of kidney function in patients with focal segmental sclerosis with no reduction in proteinuria [110]. With a model of diabetic nephropathy, pirfenidone was reported to reduce the generation of reactive oxidant

species and significantly reduce mesangial matrix expansion without affecting albuminuria. Alfrey and coworkers demonstrated that an iron-deficient diet or iron chelator provided both functional and histological protection against progression in a model of nephrotoxic serum kidney disease without affecting proteinuria [89,91]. Similarly, the study by Lin et al. showed EDTA provided protection against progression without reducing urinary protein [99]. Thus clinical studies targeted toward halting progression should focus not only on short-term studies on proteinuria, but also they would have to be of sufficient duration to evaluate the effect on renal function.

The evidence reviewed suggests the possibility of using iron chelators to halt the progression of kidney disease. The long-term use required for CKD makes oral iron chelators more attractive than parenteral medications. Currently, two oral iron chelators have been approved for human use in iron-overload states: deferasirox and deferiprone. Deferasirox has been shown to have some nephrotoxicity [111] but may nonetheless be potentially beneficial in patients with kidney disease. Deferiprone (1,2-dimethyl-3-hydroxypyridin-4-1, also known as L1) is the most extensively studied oral iron chelator and is approved for treatment of iron-overload states in Europe and India. In addition to its suitability for long-term treatment (because of oral administration), it has better tissue penetration compared to deferoxamine. The high-membrane permeability of deferiprone is well documented, as shown by its capacity to access and deplete intracellular iron pools [26]. In addition, a recent study has demonstrated its ability to remove labile iron from nuclei, endosomes, and mitochondria [26]. The major adverse effect reported so far in several thousand patients receiving deferiprone for periods of up to 14 years is transient agranulocytosis in 0.6% of patients. Based on the collective evidence to date, randomized, controlled, and double-blind trials may be warranted to evaluate the efficacy and safety of iron chelators to halt progression of CKD [112,113]. Targeting iron transport and hepcidin modulation may be effective alternative approaches to prevent and treat ferroptosis and kidney injury.

## Introduction

Cardiovascular complications are important factors influencing the mortality of patients undergoing long-term dialysis treatment. Actual cardiovascular mortality in dialysis patients exceeds the expected mortality estimated on the basis of traditional risk factors, suggesting the existence of other unknown factor(s) that accelerate cardiovascular complications in uremic patients.

The accumulation in uremic circulation of uremic toxins or metabolites has been implicated in the development of atherosclerotic lesions in uremia. The field of uremic toxins has expanded markedly in the past. Most studies on uremic toxins have focused on disorders of enzymatic biochemistry. Attention has recently turned to progressive, nonenzymatic biochemistry. In this chapter, we focus on the carbonyl amine chemistry in uremia, which results in two types of irreversible alterations of proteins: advanced glycation through the Maillard reaction and advanced lipoxidation derived from lipid peroxidation. We discuss the chemistry of various reactive carbonyl compounds (RCOs) accumulating in the uremic circulation (carbonyl stress), their patho-biochemistry particularly in relation to atherosclerosis, and, finally, the contribution of nutrition to carbonyl stress.

## Increased age and other protein modifications

In addition to the enzymatic glycosylation, a nonenzymatic process is initiated when proteins are exposed to glucose or other carbohydrates. For example, the

glycosylated hemoglobin (hemoglobin A1c, HbA<sub>1c</sub>) is formed in a nonenzymatic glycation pathway by hemoglobin's exposure to plasma glucose. This nonenzymatic process, called Maillard reaction, generates first reversible Schiff base adducts, subsequently more stable Amadori rearrangement products, and, eventually, the irreversible advanced glycation end products (AGEs) [1]. The role of AGEs in human pathology was initially highlighted in diabetes with hyperglycemia: AGEs levels are correlated with those of fructose-lysine [2], a surrogate marker of prevailing plasma glucose concentration, and also with the severity of diabetic complications [3], a finding supporting their clinical relevance.

Of note, AGEs accumulate in uremic patients to a much greater extent than in diabetics. Plasma levels of two well-known AGEs, pentosidine [4] and carboxymethyl-lysine (CML) [5], in hemodialysis patients by far exceed those in normal or diabetic subjects. Other AGE adducts also accumulate in uremia such as glyoxal-lysine dimer, methylglyoxal-lysine dimer, and imidazolone [6,7]. Among dialysis patients, diabetics and nondiabetics had similar plasma pentosidine and CML levels [4,5]. Neither pentosidine nor CML correlated with fructose-lysine levels in uremic subjects. It became thus clear that factor(s) other than hyperglycemia are critical for AGE accumulation in uremia. The fact that over 90% of plasma pentosidine and CML are bound to albumin [4,5] suggests that its accumulation does not simply result from a decreased renal clearance of AGE-modified proteins.

The second approach to irreversible protein modification in uremia derives from studies of lipid metabolism, especially lipid peroxidation. Proteins are modified not only by carbohydrates but also by lipids. For instance, proteins modified by malondialdehyde accumulate in plasma

proteins of hemodialysis patients [5]. Malondialdehyde as well as other lipid peroxidation product-modified proteins are called the advanced lipoxidation end products (ALEs) [8].

Uremia is thus characterized by irreversible nonenzymatic protein modifications by AGEs/ALEs. In renal failure patients, lipid peroxidation and advanced glycation of plasma proteins or skin collagens increase in close relation to each other [5,9].

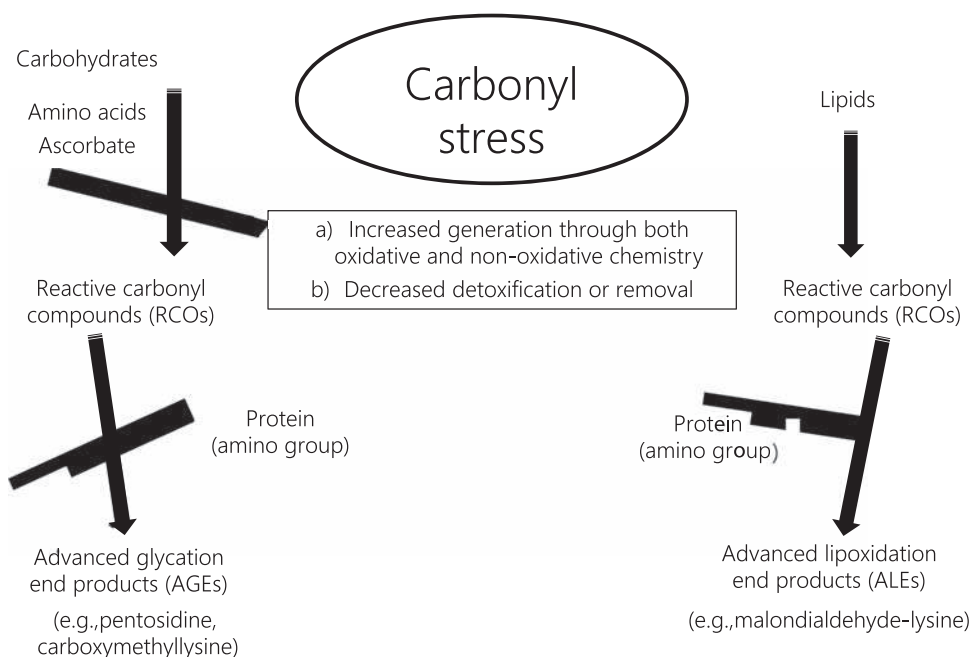

### Carbonyl stress

Both AGEs and ALEs are formed by carbonyl amine chemistry between protein amino residues and RCOs [8]. These RCOs are constantly produced during the metabolism of carbohydrates, lipids, and amino acids [10–12]. Recent studies confirm the accumulation of various RCOs derived from both carbohydrates and lipids in uremic plasma and suggest that they are indeed precursors of AGEs and ALEs [8,13,14]. The prevailing plasma pentosidine level, for example, is shown to mirror the level of its RCOs precursor [13]. The accumulation in uremic plasma of various RCOs derived from either carbohydrates or lipids as well as the subsequent carbonyl modification of proteins suggest that chronic uremia may be characterized as a state of “carbonyl stress” [14] (Fig. 9.1). AGEs/ALEs

are, therefore, not markers of hyperglycemia/hyperlipemia in uremia but represent carbonyl stress and RCO accumulation.

Two competing, but not mutually exclusive, hypotheses are considered to account for the cause of carbonyl stress [14]: an increased generation or a decreased detoxification of RCOs. First, the production of RCOs is increased by oxidative stress. Several reports point to the existence of an increased oxidative stress in uremia [15]. The uremic oxidative stress is further worsened during hemodialysis treatment, that is, activation of complement and neutrophils and generation of reactive oxygen species. A causal role of the oxidative stress in AGE and ALE formation is supported by the correlation existing in uremic serum between pentosidine and oxidative markers, such as dehydroascorbate (oxidized ascorbate) [16] and advanced oxidation protein products [17].

However, recent studies have shown that several RCOs derived from nonoxidative chemistry are also raised in uremia, suggesting the simultaneous involvement of nonoxidative chemistry in the genesis of uremic carbonyl stress. For example, the levels of 3-deoxyglucosone [18] and methylglyoxal [19], and of their protein adducts, all of which are formed independently from oxidative reactions, are increased in plasma proteins of hemodialysis patients. Carbonyl

**FIGURE 9.1** Carbonyl stress generated in uremia during the metabolism of carbohydrates, lipid, and amino acids. Both AGEs and ALEs are formed by the carbonyl amine chemistry between protein amino residues and RCOs, which are constantly produced in uremia during the metabolism of carbohydrates, lipids, and amino acids either by an increased generation of RCOs through both oxidative and nonoxidative chemistry or by a decreased detoxification or removal of RCOs. AGEs, Advanced glycation end products; ALEs, advanced lipoxidation end products; RCOs, reactive carbonyl compounds.

stress thus represents much broader derangement in the nonenzymatic biochemistry of both oxidative and nonoxidative reactions.

The alternative hypothesis is therefore proposed: the RCOs rise in uremia is derived from a decreased removal of RCOs. RCOs are detoxified by several enzymatic pathways, such as the glyoxalase pathway [20]. Reduced glutathione (GSH) and nicotinamide adenine dinucleotide phosphate (NAD(P)H) contribute to their activity. RCOs such as methylglyoxal and glyoxal react reversibly with the thiol group of glutathione and are subsequently detoxified by glyoxalases I and II into D-lactate and glutathione. NAD(P)H also replenishes glutathione by increasing the activity of glutathione reductase. Decreased levels of glutathione and NAD(P)H can, therefore, result in augmented levels of a wide range of RCOs. It is of interest to know in this context that the glutathione concentration in red blood cells and the serum activity of glutathione-dependent enzymes are significantly reduced in uremia [21].

There has been little evidence that the RCO detoxification mechanism might influence in vivo RCO formation and, therefore, serum AGE levels. Of note, a patient on hemodialysis has been identified, in whom a deficiency of glyoxalase I was associated with unusually elevated levels of AGEs (pentosidine and CML) and of their precursors [22]. This patient had suffered from recurrent cardiovascular complications despite the absence of significant risk factors. Subsequently, genetic defects of the glyoxalase I have been identified in a subpopulation of schizophrenic patients [23]. Despite normal renal function and normoglycemia, these patients are associated with strikingly elevated levels of AGEs, implicating the glyoxalase detoxification system in the actual level of AGEs in vivo.

A mechanism that regulates carbonyl stress is another issue of interest. Superoxide dismutase (SOD) and glutathione peroxidase are antioxidant enzymes involved in the metabolism of hydrogen peroxide, which accelerates carbonyl stress [12,24]. It is of note that glutathione peroxidase activities correlated inversely with pentosidine levels in uremic plasma [21]. On the other hand, the plasma extracellular SOD levels correlated with the pentosidine levels. These data suggest a link of altered redox regulation by antioxidant enzymes to an increased carbonyl stress. Furthermore, recent observation gives a new perspective in the regulation of AGE production by linking it to the prevailing effect of nitric oxide (NO) [25]: NO effectively inhibits the pentosidine generation in vitro. It is best explained by the ability of NO to scavenge carbon-centered radicals and hydroxyl radicals and, consequently, to suppress the

formation of RCOs and pentosidine. NO might be therefore implicated in the atherogenic and inflammatory effects of carbonyl stress.

### Clinical consequences of carbonyl stress

It remains to be demonstrated whether carbonyl stress is the passive result of long-term accumulation of vascular protein modifications or, alternatively, it plays an active role in the pathogenesis of atherosclerosis. Studies support the active contribution of carbonyl stress in the atherogenesis.

The levels of AGEs in arterial tissues are higher in dialysis patients than in normal subjects [26]. Both AGEs/ALEs are detectable by means of immunohistochemical approaches in the fatty streaks and in the thickened neointima of uremic patients [27]. Available evidence suggests that plasma levels of pentosidine are an independent variable of the presence of ischemic heart diseases and hypertension [28], and of left ventricular wall thickness measured by echocardiography in hemodialysis patients [29]. Skin accumulation of AGEs using the autofluorescence reader, a recently developed noninvasive device, showed that the AGE accumulation is an important predictor for arterial stiffening in ESRD subjects [30].

In vitro, AGE- and ALE-modified proteins initiate a range of cellular responses [31–35], including stimulation of monocyte chemotaxis and apoptosis, secretion of inflammatory cytokines from macrophages, proliferation of vascular smooth muscle cells, stimulation of platelet aggregation, and of vascular endothelial growth factor (VEGF) production from endothelial cells. Independently of their AGE- and ALE-mediated effects, RCOs also interfere with various cellular functions and induce not only structural but also functional alterations of proteins. For example, exposure in vitro of cultured mesothelial and endothelial cells to methylglyoxal increases mRNA and protein synthesis of VEGF [36]. Repeated intraperitoneal loads of methylglyoxal, given to rats, also increase in vivo the peritoneal membrane expression of VEGF [36]. Noteworthy in this context is the demonstration that, both in long-term peritoneal dialysis patients and in chronic uremic rat model [36,37], an increasing staining for AGEs, CML, and pentosidine is detected in peritoneal arterial walls, together with an augmented VEGF and basic fibroblast growth factor (FGF2) expression.

There are two major pathways, direct and indirect, through which carbonyl stress is sensed by cells and triggers a cascade of intracellular signal transduction. In the indirect pathway the RCOs first interact with proteins or lipids in the physiological environment surrounding the cells, which then undergo nonenzymatic glycation and lipoxidation resulting in the production of AGEs and

ALEs. They bind with the receptor(s) on cell surfaces, for example, RAGE, thereby initiating intracellular signal transduction [38]. By contrast, the direct pathway works before generation of AGEs and ALEs. The RCOs directly attack target molecules on cell surfaces or inside the cells, which initiate the subsequent signal transduction [39–43]. For example, glyoxal and methylglyoxal possess two reactive carbonyl groups to make protein aggregates by cross-linking, which may amplify the signals for tyrosine phosphorylation of cellular proteins [39]. In another model the binding of 4-hydroxynonenal, an RCO generated during lipid peroxidation, with epidermal growth factor receptor induces its clustering on the cell surface, thereby activating the mitogen-activated protein family kinases [40].

In vascular lesions an increased oxidative stress, together with altered redox regulation and decreased RCO detoxification, may increase carbonyl stress, exacerbate endothelial dysfunction, and, eventually, lead to the development of atherosclerosis.

The consequences of carbonyl stress have also been implicated in other complications associated with uremia or long-term dialysis. First, renal failure is associated with resistance to the action of calcitriol (1,25-dihydroxyvitamin D) [44], which is partly attributed to the inhibition by unknown uremic toxins of the interaction between the vitamin D receptor and vitamin D response elements [45]. Patel and coworkers [46] demonstrated that RCOs capable of Schiff base formation with lysine residues of the vitamin D receptor inhibit its interaction with the vitamin D response element. Second, dialysis-related amyloidosis is a serious bone and joint destruction associated with uremia [47]. Immunohistochemical and chemical analyses have indicated that  $\beta$ 2-microglobulin amyloid deposits are modified by carbonyl stress [48–50]. Third, the major problem associated with long-term peritoneal dialysis is the progressive deterioration of the peritoneal membrane structure and function, that is, ultrafiltration failure, which curtails its use in approximately 50% of patients within 5 years [51]. Recent studies have cast a new light on its molecular mechanism [52]. During peritoneal dialysis, RCOs resulting both from glucose PD fluid and from uremic circulation enter the peritoneum [14], modify the peritoneal membrane [53], and initiate a number of cellular responses, leading to angiogenesis and vasodilation. The latter may increase the permeability for small solutes and glucose, stimulate glucose reabsorption, and result in faster than normal dissipation of the osmotic gradient across the peritoneal membrane with an eventual loss of ultrafiltration [52].

### Nutrition and carbonyl stress

The advanced glycation of proteins has been initially unraveled by food and nutrition biochemists.

Various kinds of food indeed contain a significant amount of CML and pentosidine [54,55]. Previous studies demonstrated that although the modification of proteins with AGEs reduces the digestibility of proteins either by gaining resistance to the enzymatic digestion of proteases or by inhibiting digestive enzyme activity [55], a significant proportion of dietary AGEs are absorbed by the gastrointestinal tract into the circulation [56,57]. He et al. demonstrated that ~10% of ingested AGE-modified ovalbumin was absorbed into the rat circulation [57]. Of particular interest is the demonstration of a relationship between renal function and exogenous or food-derived AGE levels in the serum [56]. Synthesized pentosidine was given orally to both normal and uremic rats, and their kinetics in the circulation was investigated. In normal rats, plasma pentosidine rose slightly and transiently to become undetectable at 6 hours. By contrast, in rats with 6/7 nephrectomy, plasma pentosidine peaked at 3 hours and fell thereafter (calculated biological half-life of  $4.08 \pm 1.68$  hours). In bilaterally nephrectomized rats, plasma pentosidine level peaked at 12 hours and decreased subsequently (calculated biological half-life of  $47.3 \pm 10.2$  hours). The pathological contribution of exogenous or food-derived AGEs still remains unknown.

Several lines of evidence have implicated the dietary contribution to the in vivo AGE accumulation. Dietary calorie restriction reduces the accumulation of tissue AGEs without affecting the survival of the animals [58,59]. Of note is the recent report by Sell et al. that longitudinal determination of the rates of pentosidine and CML formation predicts the individual longevity in mice, and that calorie restriction retards this rate as compared to ad libitum feeding [60]. Recent study by Uribarri et al. demonstrated that dietary AGEs contribute significantly to the elevated plasma AGE levels in uremic patients [61]. More studies are required to elucidate the contribution of nutrition to the pathophysiology of carbonyl stress and to the eventual cardiovascular-associated mortality.

## Introduction

Clinical textbooks of nephrology often focus on the disturbances that alter hydrogen ion accumulation in the blood (acidosis or alkalosis) independent of the final blood pH. After all, the prompt recognition of an underlying disorder aids differential diagnosis and allows rapid intervention in many life-threatening disorders. Respiratory acidosis and alkalosis result from alterations in levels of carbon dioxide (CO<sub>2</sub>) while alterations in dietary intake as well as renal, digestive, and endocrine disorders result in alterations in noncarbonic or metabolic acid [1]. However, there are consequences when the body fails to tightly regulate blood pH at 7.40 regardless of the cause of the disorder [2]. A blood pH below 7.40 is defined as acidemia and above 7.40 is defined as alkalemia. In chronic disease the accumulation of metabolic acid or base in the body can profoundly affect long-term outcomes via effects on mineral and protein metabolism. These consequences have been best studied in models of chronic kidney disease (CKD). There is much less information about effects of acidemia in the general population and even less information about the sequela of respiratory acid and base disorders. All of the acute and many of the chronic mechanisms in response to metabolic acidosis should apply to respiratory acidosis, but there are known differences between the responses to respiratory and metabolic acidosis that have not been fully characterized.

Loss of lean body mass and bone mineral are hallmarks of metabolic acidemia in CKD, and epidemiologic data suggest that these losses correlate strongly with outcomes in patients with CKD and end-stage renal disease (ESRD) [3,4]. In addition to effects on all-cause mortality, other responses to acidemia also

appear to drive loss of renal function in patients with CKD [5]. Responses to mild chronic alkalemia, on the other hand, seem to ameliorate catabolism, but more severe alkalemia can be associated with specific acute and chronic complications primarily involving mineral metabolism. Our focus is largely on the nutritional consequences: anabolic and catabolic effects on bone and muscle, the benefits and risks of correction of acidemia on protein and bone metabolism, and the effects of high or low dietary acid loads. While the focus of this chapter is on patients with kidney disease with acidemia, we also review the evidence of the effects of acidemia and high dietary net acid load in the general population. The role of alkali compounds or of a diet providing a low net acid load or an alkaline (plant food) load for slowing progression of CKD is discussed in Chapter 19, Alkalization to Retard Progression of Chronic Kidney Disease.

## Responses to acute acidemia and alkalemia

The acute response to an acid load, such as metabolic acid from a typical Western diet or increasing respiratory acid from lowering ventilation, involves buffering by the bicarbonate–carbon dioxide system, protein anions, and bone [6]. Accepting hydrogen ions to the carboxylic side chain of proteins in acute acidosis alters the charge of these side chains and leads to changes in the function, binding, folding, and stability of enzymes, receptors, and transport proteins. This leads to the characteristic acute physiological responses seen in metabolic acidemia such as changes

in the respiratory rate, carbon dioxide–bicarbonate system, and bone buffering.

The body readily tolerates acute metabolic acidemia [7,8]. For example, the blood pH may fall below 7.2 during strenuous exercise without immediate adverse effects. In some ways, acute acidemia in the pH range of 7.2–7.4 helps the body during exercise or acute illness; cardiac index generally rises as catecholamine release is mildly stimulated by central sensing mechanisms and by increased vasodilation [7]. Increased tissue oxygen delivery occurs via this rise in cardiac index, the Bohr effect (shifting oxygen from hemoglobin to tissues), and stimulation of the respiratory drive [9]. Both innate- and cell-mediated immunities are increased in acidemia resulting in an increased ability to fight infection [10]. The liver shifts from making albumin to making acute-phase proteins of innate immunity. Endothelial and immune cell production of inflammatory chemokines and cytokines increases, as does neutrophil activation and hydrogen peroxide production.

However, studies show numerous defects in immune function when pH is below 6.9, and the responses to infection may be severely compromised [11,12]. As reviewed later, an acid pH above 7.0 seems to improve certain aspects of immune function. For example, cytokine release from macrophages in response to nitric oxide is stimulated by a fall in pH from 7.4 to 7.0, while a pH of 6.5 suppresses it [11]. The cardiovascular consequences of a more severe acute acidosis are clear in animal studies [8]. Part of the vasodilator response to acidosis is due to reduced effectiveness of catecholamine receptor signaling [13]. Below a pH of 7.1, the development of catecholamine resistance exceeds the effects of the elevation in plasma catecholamines, and cardiac index falls. The incidence of cardiac arrhythmias also rises with severe acidemia, and these effects are pronounced below a pH of 6.9 [14]. Because of the potential benefits of less severe acidemia on the circulation, recent critical care guidelines do not recommend alkali therapy for correction of acidemia (to improve hemodynamics) in patients with shock and lactic acidosis where arterial blood gas pH is 7.15 or higher [15]. In extremely strenuous competitive sports, there is concern about the adverse effects on exercise performance if the pH falls too low. Indeed, supplementation with alkali immediately before exercise appears to improve athletic performance in sports activities that induce severe lactic acidosis [16].

In contrast, acute metabolic alkalemia appears to be dangerous in the acutely ill medical or surgical patient, and the risk of death rises with increasing blood pH [17,18]. Because metabolic alkalosis is often sustained by life-threatening conditions (e.g., heart failure,

volume depletion), it is not clear to what extent the increase in mortality is due to the acute alkalosis itself or to the underlying conditions causing the alkalosis. Metabolic alkalosis decreases tissue oxygen delivery via vasoconstriction and the Bohr effect. Decreased oxygen delivery may also contribute to decreased cerebral blood flow resulting in lethargy, confusion, and worsening heart failure. In severe cases, coma and seizures may result. The respiratory center can be depressed, and alveolar ventilation decreased. However, the most feared complications of acute alkalemia are due to the lowering of ionized calcium levels as a consequence of increased albumin binding [19]. Neuromuscular irritability, which is manifested by muscle twitching, spasm, and tetany, is associated with alkalemia and is most likely calcium related. An alkaline pH has been shown to decrease aldosterone release in response to angiotensin II, resulting in vasodilation and decreased blood pressure. Myocardial contractility is blunted, as is the inotropic response to norepinephrine. As with severe acidemia, arrhythmias also increase. When the pH is greater than 7.75, the fall in ionized calcium is life-threatening, especially if hypokalemia is present; cardiac arrest commonly results. These hazards of acute alkalemia underscore the need for caution when acutely correcting acidemia. For example, an increased incidence of sudden death has been reported in hemodialysis patients when using dialysate containing higher concentrations of bicarbonate [20]. While hypokalemia may contribute to this adverse outcome, studies provide some evidence that two consequences of alkalemia, the suppression of respiration and an increase in arrhythmias, may also be involved [20,21].

### **Bone buffering and calcium homeostasis in chronic acidemia**

After the initial buffering of acids by the bicarbonate system, bone and protein serve as buffers for excess acids (Table 10.1). Calcium carbonate and phosphate in the bone matrix buffer acids (hydrogen ion; i.e., protons) to maintain the blood pH [22]; this results in the release of calcium, sodium, potassium, and phosphate ions from bone [23]. In respiratory acidosis the high carbonate concentration in blood (derived from CO<sub>2</sub>) prevents bone resorption. Metabolic acidosis also stimulates bone-absorbing osteoclasts and suppresses bone-forming osteoblasts. Acidemia has been shown in vitro to increase the activity of osteoblastic and osteoclastic genes. Proton-sensing proteins appear to play a role in this response. For example, in mice, the ovarian cancer G protein–coupled receptor, OGR-1, responds to acidemia by regulating the differentiation, metabolism, and

TABLE 10.1 Effects of chronic metabolic acidosis on bone and on protein metabolism.

1. Dissolution of bone
  - a. Direct effect of acid on bone mineral content
  - b. Increased osteoclast and decreased osteoblast activity
  - c. Increased plasma glucocorticoids
  - d. Increased serum parathyroid hormone (clinically apparent in uremia only)
  - e. Decreased plasma insulin-like growth factor-I
2. Hypercalciuria and hyperphosphaturia leading to phosphate and calcium wasting
  - a. Increased filtered load of calcium and phosphorous
  - b. Decreased tubular reabsorption of calcium and phosphorous
3. Protein malnutrition and muscle wasting
  - a. Activation of muscle proteolysis via caspase-3 and the ubiquitin–proteasome proteolytic system
    - i. Direct effect of pH
    - ii. Increased plasma glucocorticoids
    - iii. Insulin resistance in nonhepatic organs
  - b. Activation of branched-chain ketoacid dehydrogenase
    - i. Direct effect of pH
    - ii. Increased plasma glucocorticoids
  - c. Increased hepatic glutamine synthesis and renal glutamine extraction
  - d. Decreased muscle protein synthesis
    - i. Direct effect of pH
    - ii. Insulin resistance in nonhepatic organs

pH homeostasis in both osteoblasts and osteoclasts [24]. Through these proton-sensing proteins, acidemia leads to increased expression of cyclooxygenase mRNA, mRNA of the osteoclast activator, and receptor activator of nuclear factor- $\kappa$ B ligand [23]. These processes, coupled with direct inhibition of osteoid mineralization and hormonal changes (discussed later), lead to bone disease with features of osteoporosis and osteomalacia [23]. This direct effect of metabolic acidosis on bone demineralization appears to occur by different mechanisms than those induced by increased cortisol and parathyroid hormone (PTH) or decreased insulin-like growth factor-I (IGF-I) and is additive to those effects. For example, parathyroidectomy does not block the effect of metabolic acidosis on bone [25].

When renal function is normal or near normal, mobilization of calcium from bone in response to metabolic acidosis leads to hypercalciuria. The degree of hypercalciuria is directly proportional to the acid load [23]. If serum calcium rises as a result of the mobilization of bone calcium due to the acidemia, the amount of calcium filtered at the glomerulus increases. But the major effect of acidemia on renal calcium handling is a direct inhibition of tubular calcium reabsorption [26]. However, the increase in urinary calcium in metabolic acidosis occurs independently of the level of filtered calcium [27]. Respiratory acidosis causes a smaller increase in urinary calcium excretion, presumably because there is less calcium efflux from bone. Thus chronic acidemia, especially metabolic acidosis, contributes directly to negative calcium balance by causing dissolution of bone and by raising renal calcium losses.

### Increased ammoniogenesis and muscle wasting in acidemia

Acidemia directly stimulates hepatic glutamine production, which is required for renal ammoniogenesis and renal acid excretion. By accelerating muscle protein degradation, metabolic acidosis leads to release of amino acids that are used to synthesize glutamine in the liver [28]. Moreover, acidemia increases the oxidation of branched-chain amino acids (BCAA) in muscle, which provides much of the nitrogen used in the hepatic synthesis of glutamine [29]. The evidence for this latter response is that metabolic acidosis activates the rate-limiting enzyme for the irreversible decarboxylation of BCAA, branched-chain ketoacid dehydrogenase (BCKAD) in muscle, and this response accounts for BCAA degradation [29]. Plasma levels of BCAA in uremic rats are low compared to pair-fed, control rats, and these low levels are linked to increased oxidation in muscle [30]. The influence of acidosis in initiating and maintaining these processes was proven by demonstrating that adding  $\text{NaHCO}_3$  to the diet to correct the metabolic acidosis of chronic uremia restored to normal both plasma levels of BCAA and the rates of amino acid oxidation in muscle [30]. People also exhibit activation of muscle BCKAD activity in response to acidemia. Studies of normal adults confirm that an acid diet results in a 25% stimulation of BCAA decarboxylation [31].

To provide the BCAA for ammoniogenesis, acidemia provokes negative muscle protein balance by direct and indirect responses. The direct effect is seen by lowering the pH in the media of cultured myocytes,

which results in a slight decrease in protein synthesis coupled with a larger increase in protein degradation. This is consistent with a direct effect of acidemia on protein metabolism [32,33]. Correction of acidemia by inducing respiratory alkalosis reverses these effects on protein metabolism [34]. In uremic rats, there must also be an indirect effect, because the measured pH in muscle is normal in vivo in both the resting state and in the recovery from acidification [35]. This suggests that factors other than acidemia must act as signals to increase protein degradation. One of these factors is glucocorticoids that are known to be released with acidosis and to directly induce protein catabolism [28,36]. This was tested in rats where it was found that adrenalectomy blocks the effects that acidosis induces on protein and amino acid catabolism, but adding a physiologic amount of glucocorticoids restores the catabolic effect of acidosis, in vivo [37]. Both acidosis and glucocorticoids are also required to increase the activity of BCKAD and of the ubiquitin–proteasome proteolytic system in muscle and cultured myocytes [33] (see later).

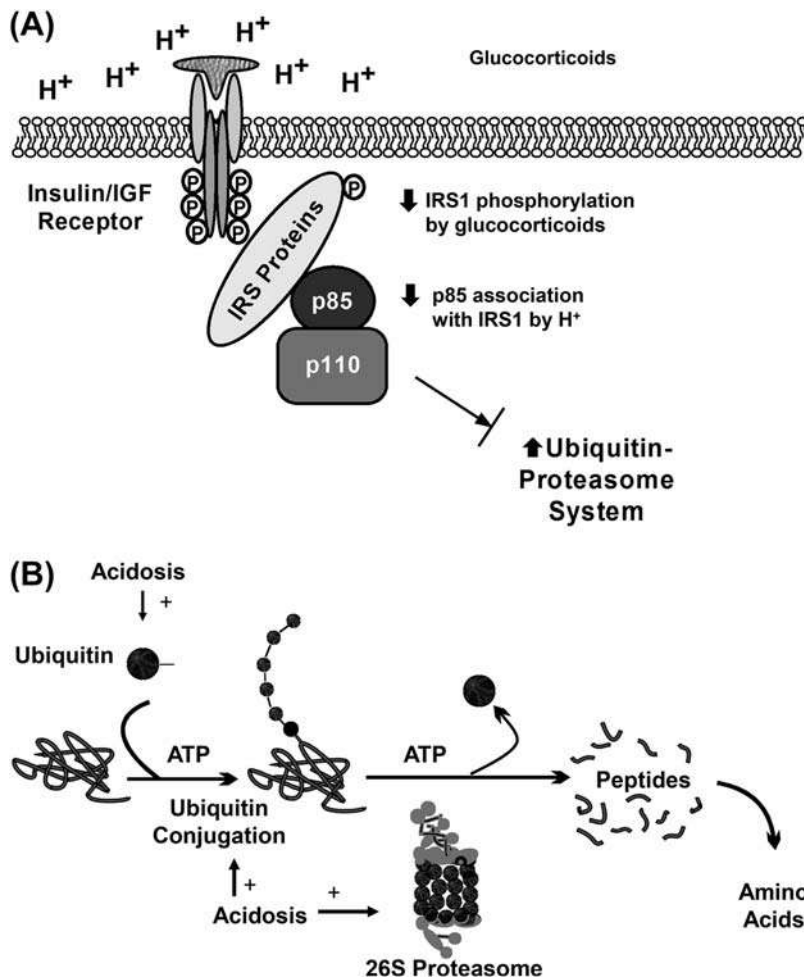

The ATP-mediated ubiquitin–proteasome pathway plays an important role in muscle degradation. In the ubiquitin–proteasome pathway, proteins are targeted for degradation by ATP-dependent conjugation of a protein to ubiquitin, a small protein found in all cells. Protein–ubiquitin conjugates are degraded in another ATP-dependent process by the 26S proteasome, a large multicatalytic, multiple subunit proteolytic complex, found in the nucleus and cytoplasm of all cells [38]. Experiments using adrenalectomized rat models, which have an absence of glucocorticoids, demonstrated that activation of the ubiquitin–proteasome pathway in acidosis requires glucocorticoids. Interestingly, neither glucocorticoid excess nor acidosis alone was sufficient to activate the ubiquitin–protein pathway; both processes are required [28,39]. Further, the response to acidosis occurs at a transcriptional level. A rise in mRNAs encoding ubiquitin and subunits of the proteasome in muscle of acidotic rats with chronic uremia and acidosis has been demonstrated [40]. In studies of cultured muscle cells and isolated muscles, metabolic acidosis increased the expression of ubiquitin mRNA and mRNA encoding the subunits of the proteasome [41]. Respiratory acidosis also upregulates the ubiquitin/proteasome system in skeletal muscle, although it is not clear if the lower pH or the increased carbon dioxide is the major driver of this response [42].

Furthermore, abnormalities in insulin and IGF-I signaling activate muscle protein degradation in the ubiquitin/proteasome system and caspase-3, a protease that disrupts the complex structure of muscle proteins to provide substrates for the ubiquitin/proteasome

system (Fig. 10.1) [41,43,44,102]. Both acidemia and glucocorticoids block intracellular signaling induced by the insulin/IGF-I receptor, but by slightly different mechanisms [44,45]. Glucocorticoids reduce insulin receptor substrate-1 phosphorylation, while acidemia has a greater effect on recruitment of the phosphoinositide 3-kinase p85 subunit to prevent downstream signaling. There is strong evidence that both glucocorticoids and a second signal that induces insulin resistance are required for muscle atrophy [46]. These signaling pathways regulate two major proteolytic systems responsible for muscle atrophy: ubiquitin/proteasome and caspase-3. The cleavage of muscle proteins by caspase-3 is a preliminary step required for muscle proteins to be digested by the ubiquitin–proteasome system [47]. Supporting this model, insulin and IGF-I suppress protein degradation in the body and insulin resistance occurs with acidemia [48,49]. The effect of acidosis to impair insulin signaling may also contribute to the small, variable decrease in muscle protein synthesis seen in acidemia [50].

Acidemia is not the sole factor driving muscle wasting in kidney disease through these pathways. For example, rats with insulin-dependent diabetes, exposed to inflammatory cytokines or treated with uremic toxins also exhibit increased muscle proteolysis via the ubiquitin–proteasome system [51]. Acidemia, diabetes, inflammatory cytokines, and other uremic toxins all induce insulin resistance. Correction of acidemia in chronically uremic rats measurably improves muscle protein degradation but does not restore it to normal levels. In contrast, the impairment of protein synthesis in uremic rats persists after correction of metabolic acidemia [36,40]. Acidemia shows synergy with other mediators of uremic muscle wasting, and the catabolic effects of acidemia appear to increase with declining renal function.

Mechanisms of the synergy between acidemia and other uremic signals on muscle protein metabolism go beyond impaired insulin and IGF-I signaling. For example, inflammation activates muscle proteolysis via the ubiquitin–proteasome system in part through myostatin, a member of the TGF- $\beta$  superfamily of secreted proteins. Myostatin, produced in skeletal muscle, acts as a powerful negative regulator of muscle mass through the type IIB activin receptor. Inflammatory cytokines and glucocorticoids increase myostatin production in skeletal muscle via the signal transducers and activators of transcription 2 and 3 (STAT 2/3) signaling [52,53]. Under the influence of interleukin (IL)-6, STAT 2/3 localize in the nucleus and bind to transcription factors driving transcription of myostatin. Blocking STAT 2/3, myostatin or their signaling in CKD reduces muscle wasting in mice. Acidemia, by itself, does not appear to be a regulator

**FIGURE 10.1** (A) Acidemia and glucocorticoids block insulin and/or IGF-I signaling to activate the ubiquitin–proteasome system in muscle. Signaling through the insulin or IGF-I receptors normally prevents muscle wasting. Acidemia and glucocorticoids work synergistically to impair signaling through the insulin receptor after binding of insulin or IGF-I. Glucocorticoids partially reduce the phosphorylation of insulin receptor substrate-1 induced by insulin binding, while acidosis blocks recruitment of the phosphoinositide 3-kinase p85 subunit to prevent downstream signaling. Impairing signaling allows the activation of the ubiquitin–proteasome system. (B) Acidosis stimulates the ubiquitin–proteasome system by affecting multiple steps. Proteins freed from the muscle fibers by caspase-3 are conjugated by ubiquitin, and the ubiquitin targets them to the proteasome where they are destroyed. Acidosis increases the amount of ubiquitin and proteasomes and also increases the conjugation of protein with ubiquitin. *IGF-I*, Insulin-like growth factor-I.

of the myostatin or STAT 2/3 pathways but increases serum glucocorticoids and IL-6 (see later). Thus acidemia would be expected to have synergy with other uremic toxins that also increase these mediators. To summarize, abundant evidence from experimental models and human studies demonstrates that metabolic acidemia accelerates irreversible oxidation of BCAA and degradation of skeletal muscle protein. However, the catabolic effect is much greater in the presence of other disturbances that also drive muscle wasting, especially those that increase glucocorticoids and inflammation.

### Hypoalbuminemia, inflammation, and innate- and cell-mediated immunities

Since catabolism is an important part of the response to infection, it is not surprising that acidosis plays a role in activating immunity. Metabolic acidosis appears to have direct and indirect effects in suppressing albumin synthesis and activating the innate immunity via the acute-phase response in the liver

(see also next paragraph). When metabolic acidosis was induced in healthy volunteers through the ingestion of ammonium chloride, there was a significant decline in the synthesis rate of albumin as well as in serum albumin levels [54]. Consistent with these findings, serum albumin and prealbumin levels increased significantly in a group of elderly patients who were given enough alkali to maintain serum bicarbonate levels at 24 mM [55]. Similar results were seen in randomized studies of patients with stage 4 CKD [56], but it has been harder to demonstrate these same results in ESRD patients. Correction of metabolic acidosis with alkali has been shown to improve serum albumin levels in some ESRD studies [57], but not in others [58]. When metabolic acidosis was corrected in patients on hemodialysis with and without inflammation, as measured by C-reactive protein (CRP), there was a reduction in protein catabolism, as measured by normalized protein nitrogen appearance (nPCR/nPNA) in both groups [59]. However, the serum albumin levels rose only in those patients with low inflammatory markers, as measured by CRP. Taken together, these studies suggest that acidemia enhances the switch

from albumin synthesis to synthesis of acute-phase response proteins in the liver, but other inflammatory signals can override correction of acidemia.

Acidemia also contributes to inflammation that reduces albumin synthesis and increases innate- and cell-mediated immunities [10,12]. Acidemia results in increased activation of the complement system, release of inflammatory cytokines (i.e., IL-1 $\beta$ , IL-6, or tumor necrosis factor- $\alpha$ ) produced by mononuclear cells, and neutrophil activation and hydrogen peroxide production. The effect of acidemia on inflammation is mediated in part by proton-sensing G protein-coupled receptors, including OGR-1, G-protein receptor 4 (GPR4), and T cell death-associated gene 8 (TDAG8) [60]. In mice, GPR4, expressed in endothelial cells, has minimal activity at pH >7.4, but its activity increases at pH 7.4 and progressively rises more as the pH falls [61]. This leads to the release of multiple inflammatory chemokines and cytokines. Reducing the GPR4 genetically or with small molecule inhibitors blunts this response. Genetic knockout of TDAG8 in mice led to diminished IL-1 $\beta$  production from glial cells in response to acidosis [24]. As with the albumin response, the effect of acidemia to increase inflammation appears to be modifiable by more powerful systemic signals. However, acute local declines in interstitial pH have been linked to critical events in chronic disease such as rupture of atherosclerotic plaques and neutrophil activation in acute asthma [10]. Whether chronic systemic acidemia can provoke these same events to drive disease progression has not been adequately studied.

### Endocrine responses to acidemia

Much attention has been given to acid-induced changes in the function of endocrine organs, including the release of cortisol, insulin, thyroxine, IGF-I, aldosterone, and PTH [62]. In many cases, activation of endocrine responses enhances the ability of bone to buffer acid and the normal kidney to excrete acid, but the same responses can cause catabolism and contribute to uremic symptoms [28,63]. In advanced kidney disease, other uremic toxins can interact with endocrine mediators, and acidemia often has an additive effect on these endocrine responses.

Acidemia increases circulating adrenal cortical hormone levels [28]. Adrenocorticotropin (ACTH) levels rise after an infusion of inorganic acids and stimulate the production of both glucocorticoids and aldosterone [64]; serum ACTH increases in acute respiratory acidosis [65]. There may also be a direct effect of low pH on the adrenal gland to stimulate the release of aldosterone, a response that depends on an increase in

intracellular calcium [66]. Since both cortisol and aldosterone increase renal acid excretion in subjects with normal renal function [67,68], the rise in ACTH can be seen as a homeostatic mechanism that acts to raise net acid excretion (NAE). Acidemia also appears to lower 11 $\beta$ -hydroxysteroid dehydrogenase activity in aldosterone-sensitive cells in the kidney. This prevents the destruction of cortisol and enhances its capacity to activate the aldosterone receptor [69]. Interestingly, acidemia is not the only cause of elevated glucocorticoid levels in uremia, since adding bicarbonate to the diet to block the development of acidosis in rats with CKD does not normalize glucocorticoid production [36]. This uremia-associated stimulation of glucocorticoid production is a crucial factor that induces abnormalities of calcium and protein metabolism [70].

Aldosterone may also play a role in the complications of uremia. With a reduction in glomerular filtration rate, increases in plasma levels of both endothelin and aldosterone have been reported in human subjects, and this increase is ameliorated with the addition of alkali [71]. Reports indicating that spironolactone can help prevent mortality in patients with congestive heart failure suggest that aldosterone might contribute to some of the cardiovascular complications seen in kidney failure [72]. Animal studies also suggest that aldosterone may be involved in progression of renal disease [73]; how endothelin may be involved in this response in humans is reviewed in Chapter 19, Alkalinization to Retard Progression of Chronic Kidney Disease. Although metabolic acidosis stimulates the production of catecholamines, glucocorticoids, aldosterone, and endothelin, supplementation of the diet of mildly hypertensive patients without kidney disease with potassium chloride is equally as effective as potassium bicarbonate at lowering blood pressure [74]. As discussed later, a net acid diet may not be a sufficiently potent stimulant of these mediators to induce clinically measurable hypertension in humans with normal renal function.

Metabolic acidosis suppresses the cellular signaling and clinical effects stimulated by both insulin and IGF-I in different ways. Acidemia does not alter islet cell secretion of insulin but does induce resistance to insulin action in peripheral tissues; reversal of metabolic acidosis improves the sensitivity of glucose metabolism to insulin [75]. In contrast, metabolic acidosis reduces growth hormone release from the pituitary and this leads to lower levels of IGF-I production. The response to an infusion of physiological concentrations of growth hormone is very mildly impaired in metabolic acidemia, and larger concentrations of growth hormone completely reverse the effects of metabolic acidemia. Two factors appear to blunt the response to administered growth hormone: first, the density of

IGF-I receptors in muscle is lowered by acidemia and, second, there is a defect in the signaling that results from the binding of IGF-I [76–78]. IGF-I resistance in uremia does not improve with the correction of metabolic acidosis suggesting that separate mechanisms (possibly involving corticosteroids) play a role [48,79]. Administration of superphysiological doses of growth hormone reduces renal nitrogen loss [80]. IGF-I (like insulin) is a major determinant of amino acid release from the muscle, although part of the beneficial response on nitrogen balance may involve improvement in plasma cortisol and/or aldosterone levels [81]. These studies point out how complex interactions occurring between different endocrine mediators can work together to either exacerbate or relieve the effects of acidemia. Abnormalities in insulin and IGF-I actions also play an important role in the growth suppression seen in children with metabolic acidosis [82].

Metabolic acidosis also suppresses adiponectin levels in subjects ingesting oral ammonium chloride. This is important because adiponectin increases insulin sensitivity and enhances its antiatherogenic and anti-inflammatory properties [83]. Beyond its effect on adiponectin, metabolic acidosis decreases secretion of leptin by adipocytes [84]. Taken together, these changes induced by metabolic acidosis should promote protein catabolism, decrease protein synthesis, and promote negative nitrogen balance. In the 1999–2000 and 2001–02 National Health and Nutrition Examination Surveys, insulin sensitivity was estimated by an index based on fasting insulin and triglyceride levels [85]. Lower serum bicarbonate levels and a higher anion gap were found to be independently associated with insulin resistance. However, insulin sensitivity was not measurably improved by bicarbonate supplementation in healthy older subjects despite the improvement in their muscle strength [86,87]. Again, it is possible that a net acid diet is insufficient to induce clinically measurable insulin resistance; frank acidemia may be necessary. Further studies will be needed to define the clinical importance of net acid diets versus frank acidemia on insulin resistance and its synergy with such other factors as obesity, glucocorticoids, and uremia.

Both metabolic and respiratory acidosis increase the sensitivity of the parathyroid gland to changes in ionized calcium and also stimulate release of PTH [88,89]. PTH has long been known to increase renal net acid secretion by inhibiting renal tubular bicarbonate resorption [90]. In patients with normal renal function, metabolic acidosis decreases proximal tubular phosphate reabsorption resulting in hypophosphatemia, and this may cause a secondary stimulation of 1,25-dihydroxyvitamin D production. The resulting rise in the activity of vitamin D counteracts the direct effects of metabolic acidosis to increase PTH secretion, so that

serum PTH concentrations are usually unchanged or even fall slightly with metabolic acidosis [91]. In ESRD, metabolic acidosis has almost no effect on phosphate excretion or 1,25-dihydroxyvitamin D production because of the loss of kidney function. Instead, metabolic acidosis increases PTH by a direct stimulatory effect on the parathyroid glands [25,88]. Importantly, correction of metabolic acidosis in patients on hemodialysis who have secondary hyperparathyroidism increases the ability of calcium to suppress the parathyroid gland's release of PTH [88]. In patients with moderate CKD, correction of metabolic acidosis with sodium bicarbonate has been shown to attenuate the rise in PTH and serum urea nitrogen levels [92].

Similar to uremia, metabolic acidosis lowers serum levels of the thyroid hormones, free T3 and T4, but, unlike uremia, may slightly raise reverse T3 (59,60) [93,94]. Resistance to the effects of thyroid-stimulating hormone (TSH) occurs within the thyroid gland and is associated with elevated levels of TSH and thyroid-releasing hormone. That these alterations in thyroid function are sensitive to metabolic acidosis is underscored by their correction with alkali [95]. While the clinical significance of this acidemia-induced mild hypothyroid-like response is unknown, it has been speculated that it plays a counter regulatory role reducing muscle proteolysis [96]. However, hypothyroidism also reduces muscle protein synthesis to leave overall muscle metabolism unchanged [97]. Furthermore, there is some evidence that hypothyroidism increases cardiovascular risk in uremia [98]. There is also little or no effect on bone. Thus while this response appears to be an exception to the overall paradigm of hormonal alterations contributing to acid-induced catabolism, the effect of acidosis on thyroid hormone may not be benign.

## Renal hypertrophy

Although metabolic acidosis increases the activity of the ubiquitin–proteasome system in muscle leading to wasting, the response to metabolic acidosis in the kidney is associated with decreased lysosomal proteolysis and renal growth. Metabolic acidosis suppresses protein breakdown in both intact renal cortex and in suspensions of isolated proximal tubules [99]. The high ammonia concentrations present in metabolic acidosis suppress lysosomal proteolysis in cultured renal tubular cells and cause increased accumulation of proteins that are normally destroyed in lysosomes [100,101]. Shechter and coworkers examined rats fed with ammonium chloride and found that there is a decrease in lysosomal cathepsin activity in the renal cortex [99].

Thus many of the amino acids that are lost from muscle during metabolic acidosis are metabolized to ammonia in the kidney, and this latter process stimulates kidney growth [103]. Much of these amino acids are first converted to glutamine in the liver that directly provides the ammonia to the kidney. Hypertrophy of the kidney is also driven by endocrine changes that occur in acidemia, including the activation of the renin–angiotensin–aldosterone system, cortisol, and endothelin [104]. All of these changes, along with the activation of complement and inflammatory pathways, may contribute to progressive kidney damage and loss of kidney function.

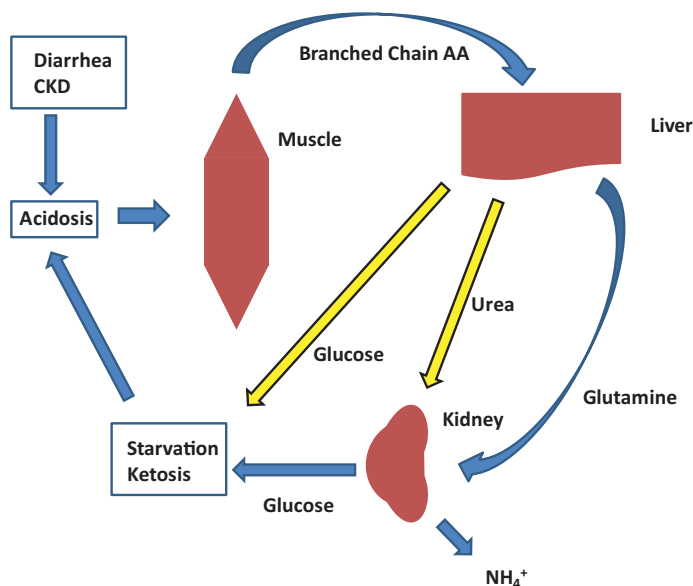

### What is the benefit of the catabolic response to metabolic acidosis?

Given the strength and sensitivity of the catabolic response to acidemia or an acid load, it is worth asking the teleological question: what outcomes could have driven the evolution of such a response? As reviewed earlier, the catabolic response to chronic acidemia helps drive the buffering and excretion of excess hydrogen ions [27]. This response is consistent with a net acid diet producing many of the same effects as frank acidemia. The calcium carbonate apatite of bone directly dissolves with acid and the hormonal responses accelerate this buffering process. The liberation of amino acids from muscle allows for increased liver glutamine production and net renal acid secretion in the form of ammonium.

A second benefit of the response to acidemia comes from the role of acidosis caused by ketone formation in the catabolic response to starvation [105,106] (Fig. 10.2). As glycogen stores are depleted during

starvation, the decrease in insulin levels triggers a transition in metabolism to ketone body formation [106,107]. The acid formed from the ketone bodies leads to changes in intracellular energy, redox sensing systems, and intracellular insulin signaling that contribute to a reduction in the basal metabolic rate [106]. Phosphate from bone and amino acids from solid organs and muscle maintain serum phosphate and amino acid levels. In the absence of ketosis, amino acids are used sparingly for energy; additionally, visceral organs, not muscle, provide the bulk of the amino acids. Oxidizing amino acids for energy is energetically unfavorable due to the high metabolic cost of urea formation [108]. In contrast, acidity from ketosis stimulates glucose formation from renal deamination of glutamine. Glucose from glutamine is energetically favorable, because nitrogen is directly excreted in the form of ammonium without further metabolism to urea [109]. Production of urea from glutamine may use 30% of the ATP generated from its metabolism, whereas ammoniogenesis may use only about 7%. Thus the integrated catabolic response to acidemia allows energy conservation in the production of glucose from BCAA in starvation.

A third potential benefit is in the proinflammatory role of acidemia in resisting infection and promoting tissue regeneration [12]. Why would acid provoke an antiinfectious response? Metabolic acidosis, whether from diarrhea, ketosis, or lactic acidosis, is among the most common laboratory abnormalities in critical illness [11]. Tissue ischemia with local acidemia occurs during systemic and local infection, trauma, and in cardiac and cerebrovascular diseases—all conditions where local inflammation acts as part of the response to injury or infection and contributes to the recovery process [10]. Acidemia liberates amino acids from

**FIGURE 10.2** Starvation and acidosis alter gluconeogenesis from amino acids. In the fed state, excess amino acids are converted to glucose via the urea cycle (yellow). Urea formation has an energetic cost of ~35% of the energy of the glucose formed. In starvation (blue), ketone formation leads to a mild acidosis enhancing the release of branched-chain amino acids from muscle. During acidosis the liver preferentially converts branched-chain amino acids to glutamine, which is deaminated in the kidney to produce ammonium and glucose. Glucose production from glutamine is much more energetically favorable than the urea cycle making this response adaptive in starvation. Metabolic acidosis from other causes activates the same pathway leading to the excretion of hydrogen ions via ammonium at the cost of amino acids. CKD, Chronic kidney disease.

muscle to enhance immune responses when fighting infection [4]. Although acidemia is beneficial in acute illness, it becomes a liability in driving inflammation in CKD [110].

### **Theories of subclinical acidemia, acid stress, or eubicarbonatemic metabolic acidosis**

Even small degrees of acidemia drive catabolism: bone mineral and muscle protein are used to buffer and aid excretion of excess acid to maintain normal intercellular and extracellular pH [111]. These responses to an acid load can also occur even when blood bicarbonate levels are within normal range: a fact that led to theories that consuming a net acid diet may have similar, but milder, effects as acidemia itself. Consuming acid loads may not rapidly lead to the full endocrine disruption of frank acidemia, but a net acid diet may play a role in the development of milder complications over a longer period of time [112]. Even in subjects without overt CKD, supplementing their net acid diet with alkali is anabolic for both muscle and bone [113,114]. These findings have led to the theories of subclinical, acid stress, or eubicarbonatemic, metabolic acidemia.

The concept of subclinical metabolic acidemia explains the beneficial effects of giving alkali to both CKD subjects and the general population who have normal serum bicarbonate levels. Administration of base can induce anabolic effects in the subset of these individuals who have an arterial blood pH below 7.40 [115]. Most studies only measure bicarbonate or total CO<sub>2</sub> where the normal range of values is often listed as extending 2 mEq/L below the mean “normal value” of 24 mEq/L [116]. Thus some individuals who have a serum bicarbonate apparently in the normal range have bicarbonates concentrations less than 24 mEq/L and thus may have pH under 7.40. The measurement of mild or subclinical acidemia may be best performed with arterial or venous blood gasses to be certain that an arterial blood PCO<sub>2</sub> less than 40 mmHg is not present. Careful studies in animal models strongly support this hypothesis: there appears to be an anabolic benefit of giving base in only mildly acidemic rats [27]. Small-scale human studies on nitrogen balance also support this concept. For example, a randomized, crossover study in eight peritoneal dialysis patients showed that a targeting arterial pH to 7.43–7.45, as compared to pH of 7.36–7.38, is associated with more positive nitrogen balance [117]. Human outcome studies adequately powered to address this issue have used mortality and CKD progression endpoints rather than bone or muscle parameters. Human epidemiologic studies measuring serum bicarbonate do not show an

effect of bicarbonate levels of 22–23 mEq/L on mortality whereas studies using arterial blood gas show a 24% higher all-cause mortality, with a bicarbonate under 25 mEq/L [118,119]. No definitive clinical trials have been designed to address this issue, but the Use of Bicarbonate in Chronic Renal Insufficiency trial is at least consistent with this hypothesis [120]. In subjects with CKD stages 3–5, correction of bicarbonate to 24–28 mEq/L from a baseline mean of 21.9 mEq/L (range 18–24) resulted in a mortality benefit.

Theories of acid stress or eubicarbonatemic metabolic acidosis extend the benefit of base to individuals with normal serum acid/base status, but who are retaining acid in their tissues [27,121]. Careful pH measurements of interstitial muscle fluid reproducibly identify individuals with serum pH >7.40 but interstitial pH <7.40 [121]. These individuals show alterations in urine NAE consistent with acidemia; they show some evidence of increased anabolism when they are supplemented with base or when their net dietary acid load is decreased. In the AASK trial, subjects with a serum bicarbonate of >22 mEq/L had a higher mortality when they had lower, not higher, net acid secretion, suggesting that the inability to rapidly excrete an acid load is associated with increased mortality [122]. Decreased urinary ammonium and urinary citrate levels appear to be key markers of individuals at a higher risk of dying. Individuals with hidden acidemia have lower urinary citrate excretion that increases with base supplementation [123]. These theories predict that renal disease, by reducing capacity for excretion of acid, prolongs the catabolic effects of dietary acid. This hypothesis could explain the increase in catabolism as CKD worsens. While there are few direct studies addressing this, analyses of the published studies suggest that the beneficial effects of correction of acidemia or lowering dietary net acid load are greater in CKD 4–5 than in CKD 1–2.

### **Estimated net endogenous acid production and the potential renal acid load**

Measurements of the effects of dietary net acid load are largely based on estimating the amount of acid the kidney must excrete to maintain homeostasis: about 40–120 mEq/day on a Western diet [124,125]. While positively charged amino acids are metabolized to acid and negatively charged ones are metabolized to base, the sulfur-containing amino acids, methionine and cysteine, produce the majority of metabolic acid. Thus the sulfur-containing amino acid content of the food is an excellent surrogate for dietary acid load, except when acid phosphates are used as food additives. The base in the diet comes largely from fruits and vegetables that contain

organic acids (citrate, acetate, malate, etc.) that liberate CO<sub>2</sub> after metabolism in the Krebs cycle [126]. However, plant fiber increases stool loss of bicarbonate and other organic bases that also contribute to the acid load. When all factors are considered, fruits and vegetables contain a large amount of net alkali; milk can be mildly acidic to alkaline depending on the species; and meat, fish, and grain have a net acid value (Table 10.2) [127]. Note that if a subject is in positive nitrogen balance (e.g., during growth in childhood, pregnancy, or exercise), some amino acids are not metabolized, lowering the net acid load of the diet.

The renal net acid load can be directly measured by 24-hour urine pH, titratable acidity, ammonium, and organic acids [125,126]. However, ammonium and organic acids can be difficult to measure, so several methods have been used to estimate dietary net acid load. Estimated *net endogenous acid production* (NEAP) is the simplest and most widely used in epidemiologic studies [128]. It uses dietary protein to estimate the sulfuric acid content of the diet and potassium to represent the fruit and vegetable content:

$$\text{Estimated NEAP (mEq/day)} = -10.2 \\ + 54.5(\text{dietary protein (g/day)/potassium (mEq/day)})$$

The usefulness of this equation arises from the large number of available epidemiologic and clinical trial databases that include dietary protein and potassium. It was derived and verified in populations consuming a Western diet and may not be accurate for other diets. It is confounded by an absolute dependence on components that have independent effects on health outcomes: protein and potassium intake.

Because accepting a hydrogen ion (i.e., by a base) leaves a cation, while releasing a hydrogen ion (i.e., by an acid) leaves an anion, differences in ions that are completely dissociated at physiologic pH (called strong ions) can be used to more accurately estimate dietary net acid load [125]. The ion composition of food can be estimated from dietary intake measures found in clinical trial databases (e.g., 24-hour recall, food frequency questionnaires) to calculate an acid load [129–131]. As dietary recall methods sometimes have quantitative errors [132], many investigators use 24-hour urine ion measurements for this estimate. The best validated equation is the *potential renal acid load* (PRAL) [129]. It estimates the sulfur content from total dietary protein with a correction for dietary phosphorous. The potential base load calculated from the strong ions is subtracted from the acid load.

$$\text{PRAL (mEq/day)} = 0.49 \times \text{protein (g/day)} \\ + 0.037 \times \text{phosphorous (mg/day)} \\ - 0.21 \times \text{potassium (mg/day)} - 0.026 \\ \times \text{magnesium (mg/day)} - 0.13 \times \text{calcium (mg/day)}$$

The PRAL, used with 24-hour urine values, also correlates with measured renal net acid load, but the correlation is not linear. Urinary excretion of organic acids (e.g., citrate) leads to loss of base, so an adjustment to PRAL based on the loss of organic acids has been proposed [133]. This correction may also account for stool losses. The correction factor (OA) for these organic acids on acid/base balance was empirically measured from NAE, OA = body surface area  $\times$  41/1.73 [133]. This formula correlates with estimated intake from food frequency questionnaires and with 24-hour urine measurements.

TABLE 10.2 Estimated potential renal acid load (PRAL) of common foods (related to 100-g edible portion).

Food	PRAL		PRAL
<b>High alkali-containing foods</b>		<b>High acid-containing meals</b>	
Raisins	−21.0	Cheddar, cheese	26.4
Black currants	−6.5	Cheese, gouda	18.6
Orange juice	−2.9	Egg, yolk	23.4
Celery	−5.2	Parmesan	34.2
Radish	−14.0	Chicken, meat only	8.7
Carrots, young	−4.9	Bean, lean only	7.8
Cauliflower	−4.0	Chocolates, milk	2.4
Spinach	−14.0	Rice, brown	12.5
Zucchini	−4.6	Trout, brown, steamed	10.8
Red wine	−2.4	Bread, white wheat	3.7

Source: Reproduced from Remer T, Manz F. Potential renal acid load of foods and its influence on urine pH. *J Am Diet Assoc* 1995;95:793.

Thus the best current estimate of renal net acid load using the 24-hour urine ion excretion is as follows:

$$\text{Estimated renal net acid load} = \text{PRAL} + \text{OA}$$

PRAL-based equations are significantly more accurate measures of net acid load than estimated NAE and are extremely useful for calculating the net acid content of individual foods. However, the equation's accuracy is also its weakness in epidemiologic studies. Because protein, fruits, and vegetables are the actual source of the acid and base in the diet, epidemiologic results using PRAL-based equations are confounded by nonacid/base effects of protein, fruit, and vegetables. As with lower protein diets, lower PRAL diets in patients with CKD were associated with a significantly reduced risk of progression to ESRD [134]. Similar to increased vegetable intake, lower PRAL diets in the general population are associated with a lower incidence of hypertension [135] and peripheral vascular disease [136], with increased physical activity and decreased frailty [137], and decreased incidence of diabetes [138]. Other endpoints have more mixed results, possibly reflecting differing effects of protein, and fruits and vegetables. In the general population, PRAL had a U-shaped association with both cardiovascular and all-cause mortality [139]. The higher mortality in low PRAL diets could reflect inadequate protein intake and the higher mortality in high PRAL diets inadequate vegetable intake. Higher PRAL in the Framingham cohort is only associated with decreased bone mineral density in older men, but not younger men or women [140]. In this same cohort, higher dietary protein intakes were associated with improved bone mineral in women but worsening bone density in older men [141], whereas vegetables are beneficial in both groups [142]. Thus the beneficial effect of higher protein intakes on bone density in older women may be masking a deleterious effect of dietary acid load on bone density [143].

Thus these studies support the benefits of a dietary pattern of adequate, but not excessive protein, in the setting of adequate intake of fruits and vegetables [144]. Lower net acid load, by preventing catabolism and limiting inflammation, may only be one of many benefits of this dietary pattern. It is frustrating, from an academic standpoint, that we cannot prove that the lower acid load leads to specific benefits, but clinically it may not matter. This pattern, which forms the basis of Dietary Approach to Systolic Hypertension and Mediterranean diets [145], gives us a powerful tool for disease prevention (see Chapter 37: Nutrition and Blood Pressure).

### Clinical implications for calcium and bone

Chronic metabolic acidosis causes increased proximal tubule citrate reabsorption leading to hypocitraturia [146].

The combination of increased renal calcium losses and hypocitraturia results in an increased incidence of nephrolithiasis [27,147,148]. In addition to the higher incidence of nephrolithiasis, preoperative metabolic acidosis has been associated with a higher incidence of osteoporosis and fractures in patients undergoing radical or partial nephrectomy [149]. Alkalemia, while associated with lower urine calcium, can raise urine pH to over 6.9 where calcium phosphate becomes less soluble leading to calcium phosphate nephrolithiasis or tubular deposition of calcium [150].

Although there are no randomized controlled trials evaluating the effect of metabolic acidosis and CKD on the growth of children, multiple observational studies and clinical experience strongly suggest that the catabolic effect of acidemia on bone is of great clinical importance in suppressing bone growth [151]. The best evidence is catch-up growth observed when acidosis is corrected in acidotic children with impaired growth. Sustained correction of acidosis results in restoration of height to normal in pediatric patients with classic renal tubular acidosis and growth impairment [152]. Consequently, correction of acidosis is recommended before initiation of growth factor therapy. Acidemia may have a particular effect on the chondrocytes in the growth plate [153]. In rats, 14 days of metabolic acidosis reduced new bone formation that was associated with a specific defect in the height of the hypertrophic zone of the growth plate. Acidosis reduced both cartilage production and bone formation.

In patients with CKD or ESRD the excess calcium mobilized from bone in the setting of acidosis remains in the extracellular space and raises the theoretical possibility of ectopic calcification. However, it has long been known that metabolic alkalosis rather than acidosis predisposes to uremic ectopic calcification [154]. In uremic rats given vitamin D, metabolic acidosis inhibits soft-tissue calcification. In the absence of metabolic acidosis, vitamin D administration to rats with a similar degree of uremia results in significant calcification in the aorta, stomach, and kidney, and higher mortality results [155]. Studies in cultured rat aortas suggest that the decrease in calcium phosphate solubility with alkaline pH, and not secondary hormonal changes, augments vascular calcification [156]. In vivo, the decrease in ionized calcium with alkalemia partly counters the lower solubility of calcium phosphate as pH rises. In normal individuals, metabolic alkalosis is not associated with ectopic calcification, despite a decrease in urinary calcium excretion [157]. The calcium-alkali syndrome (formerly called the milk-alkali syndrome) results when alkalemia is combined with excessive calcium intake [158,159]. Despite the reduction in urinary fractional excretion of calcium

and the stimulation of citrate excretion, the rise in filtered load of calcium and high urinary pH can lead to nephrocalcinosis and nephrolithiasis. In both CKD and hypercalcemic individuals with normal renal function, alkalemia appears to be a greater risk than acidemia for ectopic calcification.

In summary, correction of acidosis with alkali has been shown to improve bone mineralization and histology in acidotic patients, including those treated by hemodialysis [160]. The response of other organ systems to metabolic acidosis can lead to deleterious effects on bone mass. For example, metabolic acidosis-induced muscle catabolism can lead to decreased muscle mass that decreases the physical load on bone, leading to decreased stimulation for bone growth. Further, decreased 1,25-dihydroxyvitamin D levels, decreased growth hormone sensitivity, and increased glucocorticoid activities in response to metabolic acidosis can lead to decreased bone mass [23]. Still, it has not been documented that reduced fracture rates or other outcomes are correlated with improved acid–base status in dialysis patients. The two major concerns with alkali therapy are ectopic calcification, especially in patients with CKD or hypercalcemia, and arrhythmias in patients with hypokalemia or hypocalcemia. The observation that patients with overt alkalosis have higher mortality than those with normal serum bicarbonate suggests caution in overcorrection of acidosis with alkali [119]. Further studies will be needed to determine how to obtain the benefits of alkali therapy on bone while minimizing risks of ectopic calcification.

### **Clinical implications for protein nutrition, muscle function, and mortality**

How does metabolic acidosis affect nutritional status? It has long been felt that anorexia contributes to protein wasting in patients with metabolic acidosis, but it has been difficult to quantify the relative contribution of anorexia to protein malnutrition in acidemic people. On the other hand, strong evidence exists that excessive muscle protein catabolism due to a large increase protein degradation coupled with a smaller decrease in protein synthesis is the dominant mechanism for loss of lean body mass in metabolic acidemia. First, in rats with chronic renal failure, high-protein diets were associated with metabolic acidosis, stunted growth, and a lower efficiency of using dietary protein for growth [103]. Second, in poorly growing infants with metabolic acidosis, nitrogen excretion does not correlate with protein intake suggesting that their poor nitrogen balance is due to increased catabolism rather than decreased diet [161]. Third, normal adults with experimentally induced metabolic acidosis who are

eating a constant diet exhibit both increased oxidation of the essential BCAA and protein degradation [31]. Fourth, chronic hemodialysis and CAPD patients with acidosis exhibit excessive protein catabolism that can be suppressed when acidosis is corrected with dietary alkali supplements [162,163]. Fifth, in chronic hemodialysis patients, there is a strong linear correlation between the degree of acidosis measured just before a dialysis treatment and the free valine concentration in a muscle biopsy [164]. Treating dialysis patients with sodium bicarbonate raises the levels of BCAA in muscle; this strategy may provide more essential amino acids that can be used in the synthesis of muscle protein [165]. Besides taking supplements of sodium bicarbonate, dialysis patients experience a reduction in the severity of metabolic acidosis when they are fed a low net acid load diet. Either strategy is effective, because both improve nitrogen balance and raise the plasma concentrations of the BCCA [166,167].

There is growing evidence that exercise may ameliorate or reverse some muscle disorders related to CKD. In rat studies, muscle mass can be increased through the use of isometric exercise [168]. Exercise induces insulin-independent amino acid entry into muscle cells, reducing the catabolic effect of acid on muscle [169], and leads to the release of myokines that reduce the inflammatory effects of acidemia [170]. This combination of effects explains why a high dietary protein intake, which raises dietary PRAL, leads to anabolism when combined with resistance exercise [171]. However, acidemia may limit some of the beneficial effects of exercise on muscle. In the setting of metabolic acidosis, exercise may transiently worsen the metabolic acidosis and may decrease the normal anabolic effects of exercise [172]. Patients with CKD stages 3 and 4 with serum bicarbonate levels of 20–22 mEq/L had a greater rise in blood pressure and faster time to fatigue during rhythmic handgrip exercise when compared to those with a serum bicarbonate of >24; there was no difference in intramuscular pH between the two groups [173]. It is not clear whether these observations carry over to the general population. In competitive sports, alkali is now widely seen as a performance enhancing drug for competition [174]. However, the doses used (0.3 g of sodium bicarbonate/kg body weight) push competitors into frank alkalemia, raising the possibility of a pharmacologic effect. While base is widely used in training diets to attenuate the acid load of high-protein diets, and hormonal changes have been described, the effect on muscle anabolism of alkali administered before the exercise commences is unclear. For example, the addition of bicarbonate prior to high-intensity exercise appears to attenuate both the exercise-induced anabolic human growth hormone and catabolic cortisol responses [175].

In addition to improved muscle function, correcting acidemia may have benefits on cardiovascular fitness. In the general population, persons chronically consuming a lower PRAL diet had a higher respiratory exchange ratio during maximal effort exercise, suggesting a greater maximal oxygen uptake [176]. These findings may have relevance for CKD patients undergoing rehabilitation therapy. The association of acidosis with functional outcomes was examined in the National Health and Nutrition Examination Surveys 1999–2002. Serum bicarbonate and gait speed determined from a 20-ft timed walk were measured in over 2500 adults, age 50 years or older. Lower serum bicarbonate levels were associated with slower gait speed and decreased quadriceps strength in older adults (109) [177]. In the prospective Health, Aging, and Body Composition study, a serum bicarbonate less than 26 mEq/L was associated with increased risk of functional limitations defined as difficulty in walking 0.25 mi or climbing 10 steps [178].

In epidemiologic studies the U-shaped association between mortality and serum bicarbonate shows higher mortality with metabolic acidosis, respiratory acidosis, and metabolic alkalosis [119]. The increase in mortality with metabolic alkalosis may reflect the underlying morbid conditions that maintain a metabolic alkalosis (e.g., heart failure, volume depletion, and hyperaldosteronism) or may be the contribution of alkalemia to vascular calcification. Acidemia could similarly be an indicator of a high mortality condition, such as CKD or intestinal malabsorption. But since acidemia induces muscle wasting, decreased muscle function, and inflammation, it also drives protein-energy wasting that is associated with increased mortality [4]. However, again, it is not certain whether protein-energy wasting causes increased mortality or simply indicates underlying morbid conditions that engender the mortality.

Clearly, muscle protein reserves are critical for surviving acute infectious illnesses; functional status predicts mortality in chronic dialysis patients, and CRP is a marker for increased cardiovascular risk in these individuals. A recent clinical trial suggests that acidemia causes increased mortality in CKD patients. The Use of Bicarbonate in Chronic Renal Insufficiency was a multicenter, randomized, unblinded, pragmatic, and controlled trial that enrolled in each treatment arm approximately 370 patients with CKD stages 3–5 and with serum bicarbonate levels between 17 and 24 mEq/L [120]. The interventional arm received sufficient sodium bicarbonate to maintain the serum bicarbonate level at 24–28 mEq/L as compared to the usual treatment arm that had mean serum bicarbonate levels of about 22 mEq/L throughout the study. At 36 months of follow-up, there were significantly fewer

deaths in the interventional arm (12% or 3.1%) as compared to the usual treatment arm (25% or 6.8%). Respiratory acidosis also carries a high mortality, but it is unclear, if this reflects lung or neurologic disease versus the effects of acidosis on muscle or other tissues. For example, acidemia was associated with decreased survival in a cohort of patients with chronic obstructive pulmonary disease, but acidemia was no longer an independent risk of death when hypoxia was considered [179].

## Treating metabolic acidosis

Metabolic acidosis of CKD can be treated by decreasing intake of dietary acid-producing animal-based proteins, increasing intake of alkali-producing fruits and vegetables, and/or adding alkali salts [180] (see also [Chapter 19: Alkalization to Retard Progression of Chronic Kidney Disease](#)). Limiting protein intake is effective at correcting acidemia. Considerations on the use of low protein diets in CKD are discussed in [Chapters 16, 29, and 30](#). Dietary patterns with increased dietary vegetable intake correlate consistently with an up to 25% decline in all-cause mortality, improvements in cardiovascular endpoints, reductions in blood pressure (see [Chapter 37: Nutrition and Blood Pressure](#)), and improvements in bone health [181]. Higher fruit intake has much smaller benefits in these same areas. Increasing dietary alkali (fruits and vegetables) increased serum bicarbonate levels in patients with stages 1–3 CKD [182,183] and patients with hypertensive CKD [184] with the added benefit of decreasing blood pressure [183]. Thus for both the general population and patients with CKD stages 1–4, increasing dietary vegetable intake, with increases in fruit as tolerated, should be the first intervention and done even in patients with normal serum bicarbonate. Given the potential for hyperkalemia in patients with advanced CKD, careful monitoring of potassium is required when increasing dietary fruits and vegetables in these patients. As plant-based diets also have advantages for controlling dietary protein intake in advanced CKD, more centers are using drugs to enhance potassium excretion with high vegetable diets [185] (see also [Chapter 21: Management of Potassium in Chronic Kidney Disease and Acute Kidney Injury](#)). With fruits and starchy vegetables, diabetic patients may need supervision of portion size and timing of insulin dosing.

There is currently no clinical consensus on the optimal correction of acidemia. The abovementioned data suggest that treating acidemia to a target of pH of 7.40 (bicarbonate >24 mEq/L) is necessary and sufficient to control catabolism. But when is diet not enough, and when should we start supplemental base? Many experts recommend that nondialyzed CKD patients

and MHD and chronic peritoneal dialysis patients should start sodium bicarbonate supplements when serum bicarbonate levels are  $<22$  mEq/L, with a goal to attain a normal bicarbonate level  $\geq 24$  mEq/L [180]. This is consistent with the design of the Use of Bicarbonate in Chronic Renal Insufficiency trial [120]. However, some clinical trials have used the bottom of the normal range (serum bicarbonate = 22 mEq/L) as a treatment goal, suggesting that such conservative treatment may avoid side effects [186].

Based on these and other studies, the KDOQI Clinical Practice Guidelines for Nutrition in Chronic Kidney Disease suggest a dietary pattern of high intake of fruits and vegetables for patients with CKD 1–4 [187]. This suggestion, at level 2C, reflects the relatively low quality of the evidence on long-term outcomes in the CKD population. The KDIGO evidence rules did not allow consideration of the enormous benefit of this dietary pattern in the general population, which includes large numbers of people with CKD stages 1–3. Thus our recommendation for this dietary pattern is stronger than theirs. Further, in adults with CKD 3–5D, the KDOQI Clinical Practice Guideline recommend at the level 1C reducing net acid production through increased bicarbonate (alkali) supplementation [187]. This stronger recommendation is based on the larger benefit seen with correction of acidosis in patients with more advanced kidney disease and the extensive safety data with bicarbonate usage. We are in agreement with this recommendation.

This leaves the question of how to use alkali therapy for patients with subclinical metabolic acidosis. This may be resolved with further study. Some researchers have argued that targeting serum bicarbonate closer to the upper limit of the reference range (26–30 mEq/L) may have even greater benefit for patients with protein-energy wasting and eubicarbonatemic metabolic acidosis [188]. The major concern about such recommendations is the lack of information regarding the long-term effects of chronic metabolic alkalosis [189] and the association, whether causal or not, of alkalemia with increased in mortality in the CKD population [119]. The recent KDOQI guidelines suggest a bicarbonate goal of 24–26 mEq/L, but with the level of confidence given only as *opinion* because of the lack of adequate clinical trials [187]. However, several of the trials cited in this chapter were published after the closing date for the KDOQI evidence search, and the results of at least one of these trials suggest that a serum bicarbonate concentration of 25–27 mEq/L may be the preferred goal. As discussed earlier, there is also no consensus on how to model bicarbonate delivery with hemodialysis to adequately treat acidemia, but that acute alkalemia postdialysis should be avoided [20].

Sodium bicarbonate is the most commonly used alkali salt for treating metabolic acidosis [180]. Following oral ingestion, sodium bicarbonate neutralizes gastric acid (HCl) to form sodium chloride (NaCl),  $\text{CO}_2$ , and water. Excess bicarbonate, not neutralized by gastric acid, is absorbed from the small intestine into the systemic circulation. Oral sodium bicarbonate is relatively inexpensive and well tolerated. Side effects of sodium bicarbonate reported in CKD patients include bloating, flatulence, and belching, which can be attributed to the release of  $\text{CO}_2$ . Sodium bicarbonate may lower serum potassium making it ideal for adding to a high fruit and vegetable diet. Unlike high plant diets that provide an alkaline load, which is associated with a tendency to decrease blood pressure, oral sodium bicarbonate to correct acidemia did not lower blood pressures in clinical trials. Moreover, increased blood pressure and edema due to  $\text{Na}^+$  ingestion were not seen in these trials [56,120,182,184]. This observation is consistent with older studies showing more effective excretion of sodium when given as sodium bicarbonate than sodium chloride [190]. Lower mortality within the sodium bicarbonate treatment arm in some studies suggests greater safety [120]. However, uncontrolled blood pressure and heart failure have been exclusion criteria for these studies, so sodium bicarbonate therapy should be monitored closely in these populations. Sodium citrate, an alternative alkali salt, may have more limited use due to its potential for enhancing intestinal aluminum absorption and its taste, which is unpleasant for some people [191]. Finally, Na retention still is a concern with sodium base treatment in patients with ESRD.

Potassium bicarbonate and potassium citrate are both well tolerated in patients who are in the early stages of kidney disease, who have hypokalemia secondary to diuretics, or who have chronic gastrointestinal bicarbonate loss [192]. The availability of potassium base as citrate or bicarbonate in wax matrix, dissolvable, and liquid formulations increases the likelihood of finding a tolerable treatment. However, high alkali diets are the preferred method of delivering potassium with base. A new class of hydrochloric acid-binding resins that provide no sodium load is under development. The first clinical trial of the resin verveimer in patients with stages 3 and 4 CKD who had baseline serum bicarbonate levels of about 18 mEq/L showed their serum bicarbonate increased to approximately 22 mEq/L over 12 weeks [186]. There was a significant improvement in a questionnaire-based assessment of physical function. As with bicarbonate therapy, the most common side effects were minor gastrointestinal symptoms.

In summary, there is abundant evidence from experimental animals and cultured cell studies and from normal adults and CKD patients that metabolic acidosis is a major factor causing morbidity and mortality, especially in patients with CKD. On the other hand, healthy individuals experience milder effects from acidemia or high PRAL diets. The reduced adverse effects of an acid load in the general population are likely due to a lower exposure due to more effective renal excretion of acid and to hormonal or other metabolic signals, especially those activated by exercise, that overcome the catabolic effects of acidemia. Although the clinical evaluation of serum bicarbonate values is sometimes difficult and optimal bicarbonate goals are not known, the treatment of acidemia is straightforward and often results in a gain of weight, increased muscle mass, improved functional status, and improved mortality in CKD patients [191]. In short, the simple acts of restricting dietary protein or increasing fruit and vegetable consumption (before the start of dialysis) or supplementing alkali (before or after the start of dialysis) can reduce the risk of major complications of the metabolic acidosis of CKD.

# The gut microbiome and the kidney

Renu Regunathan-Shenk<sup>1</sup>, Neal B. Shah<sup>2</sup> and Dominic S. Raj<sup>1</sup>

<sup>1</sup>Division of Kidney Disease and Hypertension, George Washington University School of Medicine and Health Sciences, Washington, DC, United States of America <sup>2</sup>Division of Medicine, John Hopkins Bayview Medical Center, Baltimore, MD, United States of America

We should think of each host and its parasites as a super-organism with the respective genomes yoked into a chimera of sorts.

Nobel Laureate Joshua Lederberg [1]

3.4 mg/dL (with eGFR 18 mL/min/1.73 m<sup>2</sup>); glucose, 82 mg/dL; calcium, 8.3 mg/dL; phosphate, 6.2 mg/dL; and albumin, 3.8 g/L.

## Case vignette

A 65-year-old man with chronic kidney disease (CKD) stage G4A1 presented to the emergency room with chronic constipation and lethargy. Clinical exam was remarkable for distended abdomen with hypoactive bowel sounds and generalized muscle weakness. Laboratory investigation revealed sodium, 138 mEq/L; potassium, 6.2 mEq/L; chloride, 115 mEq/L; bicarbonate, 16 mEq/L; anion gap, 14; serum urea nitrogen, 67 mg/dL; creatinine, 3.8 mg/dL (corresponding to eGFR 16 mL/min/1.73 m<sup>2</sup> by Modification of Diet in Renal Disease (MDRD) equation); glucose, 100 mg/dL; calcium, 8.1 mg/dL; phosphate, 7.1 mg/dL; albumin, 3.6 g/L; white blood cell count,  $8.1 \times 10^9$ /L; and hemoglobin, 10.1 g/dL. Abdominal computerized tomography (CT) showed abundance of fecal matter in a dilated rectum and sigmoid colon. After disimpaction with enema and laxatives, the patient felt better and was discharged from the emergency room with the recommendation to take stool softeners on a regular basis.

After 2 months, he was seen in the outpatient nephrology clinic. He appeared energetic and stated that he was taking a daily prebiotic, p-inulin, and along with a laxative as needed. Repeat laboratory evaluation showed sodium, 139 mEq/L; potassium, 4.0 mEq/L; chloride, 110 mEq/L; bicarbonate, 20 mEq/L; anion gap, 11; serum urea nitrogen, 51 mg/dL; serum creatinine,

## Introduction to the gut microbiome

Approximately  $10^{14}$  bacteria reside in the human gut, providing enormous metabolic potential [2–4]. The term “microbiota” refers to the group of bacteria, bacteriophages, fungi, protozoa, and viruses that live in or on the human body. On average, an individual’s gut microbiota is composed of 500–1000 unique bacterial species [5]. More than 95% of microbial species are unable to grow on culture medium; however, the development of DNA-based techniques in the 1980s has led to the discovery of previously unknown microbiota. The two main approaches used for analyzing the microbiome are 16S ribosomal RNA (rRNA) gene amplicons and shotgun metagenomics. The 16S rRNA subunit gene is composed of highly conserved ubiquitous sequences and has regions that varied with greater or lesser frequency during evolution. The 16S rRNA sequencing provides excellent species level identifications but is generally insufficient to identify strain-level differences. Similar gene marker amplicon sequences are clustered as operational taxonomic units (OTUs). In contrast, metagenomic analysis provides an assessment of the functional attributes of the microbiome. The application of high-throughput sequencing has unveiled the enormous diversity, functional and intraindividual stability, interindividual variability, and influence of host genetics and environmental factors shaping microbiome composition [6,7].

The bacterial genome, defined as the collective genomes of the microbiota, vastly outnumbers the human microbiome and has coevolved with humans to complement activities such as degradation of bile acids [8], synthesis of vitamins and amino acids [9], metabolism of complex polysaccharides [10], maturation of the immune system [11], and degradation of dietary oxalates [12]. Postnatal colonization of the intestine educates our immune system and reduces allergic responses to food and environmental antigens [11]. Studies have shown that individuals living in the same region, belonging to the same family, or having similar diets share similar phylogenetic composition of the gut microbiome [13]. The gut microbiome appears to adapt to the needs of the host, providing the metabolic functions needed to process its diet [14]. It generally remains stable over time. A study characterizing the long-term stability of the human gut microbiota using low error amplicon sequencing of fecal samples from 37 healthy adults collected for over 5 years demonstrated remarkably stable microbiota in individuals and between family members over the follow-up period. These findings emphasize the importance of early gut colonizers acquired from parents and siblings, and their potential life-long effect on our health and disease [15].

In humans the predominant intestinal microbial groups include *Bacteroidetes*, *Firmicutes*, and *Actinobacteria*. Other phyla, such as *Proteobacteria*, *Verrucomicrobia*, *Cyanobacteria*, *Fusobacteria*, *Spirochaetes*, and *TM7* are also present in smaller proportions [16,17]. Each species of bacteria colonizes a different area of the gastrointestinal tract (Table 11.1). Together, gut microbiota and human hosts exist in

symbiosis, a state of mutual harmony. Disruption in the intestinal membrane barrier and increased permeability to gut-derived toxins results in endotoxemia-mediated inflammation which has been observed in various chronic diseases, including CKD, metabolic bone disease [22], diabetes [23], obesity [23], nephrolithiasis [24], hypertension [25,26], and cardiovascular disease [27–29].

## The Gut Microbiome, Dysbiosis, and CKD

### Microbiota and the maintenance of the intestinal epithelial barrier

The intestinal epithelium serves as a dynamic barrier, allowing the absorption of nutrients while also preventing the translocation of antigens and pathogens (Fig. 11.1). A single layer of columnar epithelial cells separates the intestinal lumen from the underlying lamina propria [30]. These epithelial cells are bound together by tight junctions [31]. Commensal bacteria maintain the integrity of the barrier by several mechanisms, including restoration of tight junction protein structure [32], introduction of epithelial heat-shock proteins [33,34], upregulation of mucin genes [35], competition with pathogenic bacteria for binding to epithelial cells [36], and secretion of antimicrobial peptides [37]. The microbiota also protect the epithelial barrier by suppressing intestinal inflammation. Commensal gut bacteria interact with Toll-like receptors (TLRs), a family of pattern-recognition receptors who sense microbial infection through the binding of ligands and then initiate immune defense responses. For example, the

TABLE 11.1 Distribution and composition of the microbiota along the gastrointestinal tract.

Gastrointestinal tract	Healthy population		CKD/ESRD population
	Dominant species	Microbial number (cells/g)	Alterations from normal microbiota
Stomach	<i>Lactobacillus</i> , <i>Helicobacter</i>	$10^1$	
Duodenum	<i>Staphylococcus</i> , <i>Streptococcus</i>	$10^3$	Human studies: increased counts ( $10^6$ – $10^7$ ) [18]
Jejunum	<i>Enterococcus</i> , <i>Streptococcus</i> , <i>Lactobacillus</i>	$10^4$	Human studies: increased counts ( $10^6$ – $10^7$ ) [18]
Ileum	<i>Enterobacteriaceae</i> , <i>Bacteroides</i> , <i>Clostridium</i> segmented filamentous bacteria	$10^7$	
Colon	<i>Firmicutes</i> , <i>Bacteroidetes</i> , <i>Actinobacteria</i> , <i>Proteobacteria</i> , <i>Clostridium</i> , <i>Lactobacillaceae</i> , <i>Prevotellaceae</i> , <i>Fusobacteria</i> , <i>TM7</i>	$10^{12}$	Human studies: overgrowth of aerobic bacteria (about 100 times) [19], decreased <i>Bifidobacteria</i> and higher <i>Clostridium perfringens</i> [19], lower species richness [20]. Experimental animal studies: increased <i>Proteobacteria</i> , <i>Enterobacteriaceae</i> , <i>Escherichia</i> , <i>Enterobacter</i> , <i>Acinetobacter</i> , <i>Proteus</i> , and <i>Proteus</i> spp., and decreased <i>Lactobacillus</i> , <i>Bifidobacterium</i> spp. [21], and decreased <i>Lactobacillaceae</i> and <i>Prevotellaceae</i> [21]

stimulation of TLR2 promotes B-mediated cell survival via myeloid differentiation factor 88, preserving tight junction assembly against stress-induced damage [38].

## Dysbiosis and CKD

Dysbiosis refers to an imbalance in the gut microbial community leading to qualitative and quantitative alterations in its activities [39]. Gut dysbiosis has been associated with several diseases such as obesity [40], type 2 diabetes mellitus [41], inflammatory bowel disease [42], and cardiovascular disease [43–46]. One of the main factors leading to dysbiosis is antibiotic use, which decreases the diversity and relative quantities of bacterial groups even once therapy has completed [47–49]. Diet has a significant impact on the health of the microbiome; for example, fiber intake has been shown to directly interact with gut microbes, leading to the production of beneficial metabolites [50], and ingestion of artificial sweeteners has been shown to negatively impact the composition of the gut microbiota [51]. Several studies have shown that patients with CKD exhibit changes in microbiome composition [20,52,53]. For example, Vaziri et al. found that

190 microbial OTUs differed significantly in abundance between end-stage renal disease (ESRD) patients and healthy controls [20]. Demonstrated factors in dysbiosis in this population include less consumption of fiber [54], iron treatment [55], delayed intestinal transit time [56], antibiotic use, and attenuated protein assimilation [57].

When compared to healthy controls, CKD patients exhibit differences in the colonization of aerobic and anaerobic organisms (Table 11.1). In general, low bacterial diversity, an increase in *Proteobacteria*, *Enterobacteria*, and *Clostridium perfringens*, and a decrease in *Lactobacillus* and *Bifidobacterium* species in the colonic gut have been observed in CKD patients versus healthy controls [58]. The duodenum and jejunum, which are not normally heavily colonized in healthy persons, show greatly increased aerobic ( $10^6$  bacteria/mL) and anaerobic ( $10^7$  bacteria/mL) colonization [18]. Stool microbiome analysis in ESRD patients has shown an increase in bacteria families with urease, *p*-cresyl, and indole-forming enzymes and a reduction in short-chain fatty acid (SCFA)-producing commensals [59]. Other studies comparing ESRD patients to healthy controls have shown a 100-time increase in the number of aerobic bacteria such as *Enterobacteria* and *Enterococci* species in hemodialysis patients [19].

## CKD and the gut barrier function

Uremia appears to increase intestinal permeability in both murine models and CKD patients [60,61]. Studies in uremic rats have demonstrated systemic oxidative stress, azotemia, and marked depletion of key protein components of the epithelial tight junction (claudin 1, occludin, ZO1) in the stomach, jejunum, and ileum [62]. They have also shown penetration of bacteria across the intestinal wall and into the mesenteric lymph nodes [21,63]. These disruptions can lead to chronic damage to the gut barrier. Autopsy studies of hemodialysis patients have revealed decrease in villous height, inflammation in the intestinal lamina propria, liver fibrosis, and signs of cardiovascular disease [63].

## Uremic toxins and CKD

Uremic toxins are generated from protein metabolism and adversely affect biologic functions (Fig. 11.2). In 1965 Einshieber and Carter demonstrated that germfree anephric mice survived longer than anephric mice with an intact gut microbiome [64]. Similarly, a study of dialysis patients with and without colons showed that these toxins were minimal or absent in patients without colons [65]. The intestinal origin of uremic toxins has been demonstrated in several studies. For example, protein catabolism generates ammonia, which is converted into urea via

the ornithine–urea cycle. While mammals cannot metabolize urea, gut bacteria expressing the enzyme urease can cleave urea into ammonia and carbon dioxide [66]. Some of this ammonia can then be used for the synthesis of amino acids by the microbes or can enter the host circulation [67]. Ammonia can also be generated by microbial fermentation of the amino acids glutamine, serine, threonine, and glycine. In high levels, ammonia and urea are toxic to cells and have been shown to disrupt the intestinal barrier functions and epithelial tight junctions [68–70]. Gut microbes have been shown to generate other uremic toxins such as *p*-cresol, phenol, and indole through the fermentation of the amino acids phenylalanine, tyrosine, and tryptophan [71].

Of note, uremic toxins are difficult to remove via hemodialysis as they are largely protein-bound, and metabolism of phenols and aromatics may be affected by antibiotic use [72]. Important uremic toxins, as well as their related bacteria and pathogenic mechanisms, are described in Table 11.2. The following sections highlight gut-derived metabolites that have strong associations with CKD, cardiovascular disease, and other chronic conditions.

## Indoxyl sulfate

Indoles are an aromatic group of compounds containing a pyrrole ring. Bacterial metabolism of

FIGURE 11.2 Schematic showing some of the major toxic metabolites originating from synthesis by dysbiotic gut microbiome and potential pathways linking their accumulations to pathophysiological consequences in CKD. TABLE 11.2 Gut microbiome—derived uremic toxins.

Group	Solute	Source	Related bacteria	Mechanism of disease	References
Carbamide	Ammonia and urea	Ammonia, the end product of protein catabolism, is converted to urea by ornithine–urea cycle. Gut bacteria expressing urease cleave urea into ammonia and carbon dioxide	Urease is produced by several bacterial species, including <i>Clostridium</i> spp., <i>Enterococcus</i> , <i>Shigella</i> , and <i>Escherichia coli</i>	High concentration of ammonia changes the luminal pH causing uremic enterocolitis; amino acid catabolism leads to the formation of sulfides, phenolic compounds, and amines, which are inflammatory and/or precursors to the formation of carcinogens	[7,66,67]
Guanidine	Creatinine, guanidine, and uric acid	Colonic bacteria degrade creatinine in gut. Guanidine is produced by creatinine metabolism via <i>Pseudomonas stutzeri</i> . Intestinal organisms can degrade urate, generating allantoin, allantoic acid, urea, and ammonia		Guanidine accumulation in CKD increases mortality as shown in animal studies	[73–77]
Guanidine	1-Methylguanidine	Metabolism of creatinine	<i>P. stutzeri</i>	Accumulates in CKD and is considered a uremic toxin; administration to rats with kidney failure demonstrated a dose-dependent increase in mortality	[78–80]
Amine	TMAO	Endogenous generation; bacterial metabolism of dietary lipid phosphatidylcholine, carnitine, and choline	Order <i>Clostridiales</i> and genus <i>Ruminococcus</i>	Increases the progression of renal disease and mortality in CKD; increases tubulointerstitial fibrosis and collagen deposition; increases phosphorylation of Smad3, which regulates the profibrotic transforming growth factor- $\beta$ /Smad3 signaling	[81–83]
Amino acid	Homocysteine	Endogenous generation; intestinal bacteria lower homocysteine by production of folic acid	<i>Bifidobacterium</i> spp.	Increases risk of Cardiovascular Disease (CVD) and death; increases oxidative stress (through the production of reactive oxygen species), binds to nitric oxide, produces homocysteinylated proteins, and leads to the accumulation of its precursor, S-adenosylhomocysteine, a potent inhibitor of biological transmethylation	[84]
D-Amino acid	D-Lactic acid	Ingestion; endogenous generation, and bacterial production	<i>Enterococcus</i> and <i>Streptococcus</i> spp.	Involved in D-lactic acidosis; associated with neurotoxic effects and encephalopathic symptoms	[18,85]
Dicarboxylic acid	Oxalate	Ingestion and endogenous generation, certain intestinal bacteria have oxalate degrading potency to remove oxalate	<i>Oxalobacter formigenes</i> , <i>Bifidobacterium lactis</i> , <i>Enterococcus faecalis</i> , and <i>Eubacterium lentum</i>	Hyperoxaluria leads to urolithiasis; increased endothelial cell replication and migration leading to atherosclerosis	[86]
Phenol	p-Cresol sulfate	Bacterial metabolism of tyrosine and phenylalanine	<i>Clostridium difficile</i> , <i>Faecalibacterium prausnitzii</i> , <i>Bifidobacterium</i> , <i>Subdoligranulum</i> , <i>Lactobacillus</i>	Increases progression of CKD, CVD, and mortality in hemodialysis patients; decreased cytokine-stimulated expression of endothelial adhesion molecules; increases endothelial permeability	[87–89]
Indole	Indoxyl sulfate	Bacterial metabolism of tryptophan	<i>Clostridium sporogenes</i> , <i>E. coli</i>	Increases vascular stiffness, aortic calcification, and cardiovascular mortality; increases oxidative stress in endothelial cells; increases vascular smooth muscle cell proliferation; increases expression of genes related to tubulointerstitial	[90–95]

(Continued)

TABLE 11.2 (Continued)

Group	Solute	Source	Related bacteria	Mechanism of disease	References
Monocarboxylic acid	Indole-3-acetic acid	Endogenous; bacterial metabolism of tryptophan	<i>C. sporogenes</i> , <i>Clostridium bartlettii</i> , <i>E. coli</i>	fibrosis; associated with nephrotoxicity  Induce glomerular sclerosis and interstitial fibrosis in subtotally nephrectomized rats, thus contributing to the progression of CKD; serum Indole-3-Acetic Acid (IAA) is a significant predictor of mortality and cardiovascular events in patients with CKD; induces proinflammatory enzyme cyclooxygenase-2 and oxidative stress	[96,97]
Monocarboxylic acid	Phenylacetic acid	Endogenous; bacterial metabolism of phenylalanine and tryptophan	<i>Clostridium</i> spp., <i>Bacteroides</i> spp.	Toxic; induces nausea, vomiting, diarrhea, and convulsion; associated with impaired immunoregulation, increased oxidative stress, and osteoblast dysfunction; shown to causes renal tubular damage in dogs	[98–101]
Carboxylic acid	Hippuric acid	Ingestion, bacterial metabolism of aromatic compounds and polyphenols	<i>Clostridia</i> spp.	Nontoxic; ↑ the anion gap acidosis; may cause glucose intolerance and interfere with erythropoiesis and platelet cyclo-oxygenase activity	[102–104]
Polyamines	Polyamines	Many polyamines are generated by microbiota from precursor amino acids		Polyamines play a role in the lack of tissue responses to hormones in uremia. Associated with erythropoietin inhibition, anemia of CKD	[101,104]

CKD, Chronic kidney disease; TMAO, trimethylamine N-oxide.

tryptophan generates more than 600 indoles in the gut, which are then absorbed and conjugated with sulfate by the liver [105]. Indoxyl sulfate (IS) is an indole that is highly protein-bound and associated with CKD progression, cardiovascular disease, and low-turnover bone disease [106,107]. IS is normally cleared by the proximal tubules of the kidneys and is transported via organic anion transports 1 and 3 (OAT1 and OAT3). In experimental models of kidney failure, OAT1 and OAT3 expression is reduced [108], leading to the buildup of IS in proximal tubular cells [109]. Accumulation of IS in proximal tubular cells has been associated with the activation of NF-κB and plasminogen activator inhibitor type 1 expression [109,110]. Following administration to uremic rats, IS also increases gene expression of transforming growth factor beta-1 (TGFβ1) and tissue inhibitor of metalloproteinase, both of which mediate tubulointerstitial fibrosis [111].

IS is also associated with increase all cause and cardiovascular mortality in CKD patients, as well as increased aortic calcification and vascular stiffness [112–114]. Investigational studies have demonstrated that IS induces vascular smooth muscle cell proliferation [90],

attenuates endothelial cell repair mechanisms [114], increases oxidative stress in endothelial cells [114], and enhances shedding of endothelial microparticles [115]. IS appears to disrupt oxygen sensing in erythropoietin producing cells, decreasing erythropoietin production [116]. Furthermore, IS affects bone health in a myriad of ways; it is taken up by osteoblasts, increases oxidative stress, decreases parathyroid hormone receptor expression, and inhibits osteoclast function [117,118].

### *p*-Cresol sulfate

*p*-Cresol sulfate (also called *p*-cresyl sulfate or PCS) is a uremic retention solute and toxin which depends on tubular secretion via specific transporters for excretion out of the kidney [91,92,96,119,120]. It accumulates in CKD, leading to progressive renal disease through activation of the TGF/SMAD pathway, activation of the intrarenal renin angiotensin system, and possibly epithelial mesenchymal transformation causing renal fibrosis [121]. In a study of nephrectomized rats, administration of PCS caused significant renal tubular damage in 5/6 rats by increasing oxidative stress and inflammatory cytokines [82]. PCS is also associated

FIGURE 11.3 Schematic representation of the link between diet, gut microbiota, TMAO and the clinical manifestations of this uremic toxin. Source: Adapted from Velasquez et al. Trimethylamine N-oxide: the good, the bad and the unknown. *Toxins (Basel)* 2016;8(11).

with cardiovascular disease and increased all-cause mortality in CKD and ESRD patients [122–124], as well as insulin resistance and cachexia [125].

### Trimethylamine N-oxide

Trimethylamine N-oxide (TMAO) is a metabolite generated from gut microbial degradation of choline, betaine, and carnitine. Carnitine is a metabolite found in red meat.

Microbial enzymes transform choline and L-carnitine into trimethylamine (TMA), a volatile gas, which then travels to the liver via the portal circulation, where it is transformed into TMAO [126] (Fig. 11.3). In a landmark study, Wang et al. screened more than 2000 metabolites in 75 patients with cardiovascular disease, identifying an association between the metabolites TMAO, choline, and betaine and heart disease [44]. Elevated TMAO levels are a predictor of increased long-term mortality in patients

with congestive heart failure independent of traditional risk factors [127]. How TMAO promotes atherosclerosis remains elusive; proposed mechanisms include alteration of cholesterol and sterol metabolism, promotion of foam cell formation, and alterations in bile acid metabolism and sterol transporters in the liver and intestine [44,128].

Patients with CKD have an elevated level of TMAO and these increased levels are associated with increased risk of death. In animal models, ingestion of TMAO and choline was associated with significant increase in SMAD3 phosphorylation and led to tubulointerstitial fibrosis and collagen deposition [128].

## Endotoxin

Endotoxin is a phospholipid that forms the outer membrane of most Gram-negative bacteria. Circulating endotoxin binds lipopolysaccharide-binding protein, forming a complex that interacts with the MD-2 part of TLR4, anchored by the CD14 receptor [129]. Binding of CD14 stimulates activation of NF- $\kappa$ B as well as the production of inflammatory cytokines [130]. It has been proposed that endotoxin translocation from the gut is one of the causes of inflammation in CKD. Studies have demonstrated that soluble CD14 is associated with CKD progression, Cardiovascular Disease (CVD), and mortality in patients with kidney disease [131–133]. Endotoxin has also been implicated in the pathogenesis of atherosclerosis by mediating endothelial cell injury, boosting recruitment of monocytes, transforming macrophages to foam cells, and activating coagulant activity [134,135]. Additionally, murine models have shown that endotoxin may be a trigger of insulin resistance, obesity, and diabetes [136].

## Short-chain fatty acids

Dysbiosis can also lead to decreased production of beneficial metabolites, such as SCFA. SCFAs are 1- to 6-carbon aliphatic organic acids generated by gut anaerobic fermentation of dietary polysaccharides. SCFAs include acetate, propionate, and butyrate, which can enter the systemic circulation via passive diffusion and active transport through colonocyte cells. Butyrate is the primary source of energy for colonocytes and is thought to be integral to maintaining the health of the intestinal epithelium. SCFAs affect a range of host functions, including gut motility, immune regulation, energy metabolism, and blood pressure regulation, through the activation of G protein-coupled receptors [137]. In a germ-free mouse model, treatment with SCFA reduced ischemia reperfusion injury and, thus, SCFA may be an important mediator of acute kidney injury [138,139].

## Gut microbiome and hypertension

Dietary salt intake, antibiotic use, regulation of serotonin and norepinephrine, renal sodium excretion, and metabolites such as TMAO are all known to influence the development of hypertension via the modulation of the gut microbiota. Animal studies have supported a causal effect of gut microbiota on blood pressure [140]. For example, normotensive rats developed hypertension following the transplantation of fecal contents from hypertensive rats [141]. Gut microbiome analysis of participants of the CARDIA study (Coronary Artery Risk Development in Young Adults) showed inverse association of hypertension with bacterial richness (alpha diversity) and several genera associated with hypertension [142]. Other studies have conclusively shown depletion of *Lactobacillus* species, particularly *Lactobacillus murinus*, with high-salt diet consumption with resultant hypertension. Daily treatment with *L. murinus* was shown to prevent high-salt diet-induced generation of T<sub>H</sub>17 cells and consequently ameliorate salt-sensitive hypertension [25].

SCFA produced by the gut microbiota activate two orphan G protein-coupled receptors, GPR41 and GPR43, and olfactory receptor 78 (Olfr78) [26]. The increase in blood pressure caused by SCFA-induced renin release from the afferent arteriole is mediated by Olfr78 [26]. This, in turn, can be counteracted by the vasodilatory action of GPR43 [26].

## Targeted interventions to treat dysbiosis in CKD/ESRD

Several targeted interventions to reestablish intestinal symbiosis, neutralize bacterial endotoxins, or adsorb gut-derived uremic toxins have been developed. Human and animal studies suggest that prebiotics, synbiotics, and probiotics as well as dietary modifications may have therapeutic roles in maintaining metabolically balanced gut microbiota, as well as attenuating the progression of CKD and uremia-associated complications [143].

## Prebiotics

A prebiotic is a substrate that is metabolized by selected beneficial host microorganisms [144]. While this definition applies to body sites outside of the gastrointestinal tract and to diverse categories other than food, most studies have been done using prebiotic foods such as inulin, fructo-oligosaccharides, galacto-oligosaccharides, soya-oligosaccharides, xylo-oligosaccharides, and pyrodextrins which nourish the gut microbiota. Many

prebiotics promote the growth of *Bifidobacteria* in the gut, improving gut health and reducing inflammatory diseases [145]. The use of prebiotics in the form of fermentable fibers in CKD patients has been shown to reduce serum urea nitrogen while increasing fecal nitrogen content [146,147]. In contrast, Poesen et al. used prebiotic arabinoxylan oligosaccharide in nondialysis CKD patients and found no significant effects on uremic solutes [148]. Further research must be done to clarify the role of prebiotics in reducing uremic toxins.

## Probiotics

The World Health Organization defines probiotics as “live microorganisms which when administered in adequate amounts confer a health benefit on the host” [149]. Unlike prebiotics, which stimulate the growth of host’s own beneficial microbes, probiotics are directly supplemented beneficial bacteria commonly in the form of *Lactobacillus* and *Bifidobacterium* [150]. Several studies have demonstrated that probiotic use can decrease the level of uremic toxins and improve renal survival. A placebo-controlled blinded study in nephrectomized rats randomized to different probiotic regimens showed improvement in uremic toxins, renal function, and survival in rats who received *Bacillus pasteurii* or *Sporolac* regimens [151]. *Lactobacillus acidophilus* use in hemodialysis patients has been associated with reduction in the gut uremic toxins dimethylamine and nitrosodimethylamine [18]. *Bifidobacterium longum* has been associated with delay of ESRD in late-stage CKD patients as well as reduction of IS levels in hemodialysis patients [152,153]. A 6-month prospective multicentric trial conducted in stages 3 and 4 CKD patients using a probiotic mixture of *L. acidophilus*, *B. longum*, and *Streptococcus thermophilus* showed an improvement in BUN and uric acid levels, with approximately half of the patients demonstrating an improvement in creatinine levels and overall improvement in quality of life and well-being [154]. Wang et al. conducted a randomized clinical trial in peritoneal dialysis patients with a probiotic capsule containing *Bifidobacterium bifidum*, *Bifidobacterium catenulatum*, *B. longum*, and *Lactobacillus plantarum* strains for 6 months compared with placebo. A reduction in serum endotoxin levels and certain proinflammatory cytokines as well as preservation of residual renal function was observed in the probiotic group [155]. The use of *Lactobacillus* and *Bifidobacterium* in hemodialysis patients has shown beneficial effects on glucose homeostasis and reduction in inflammation in diabetics [156]. In contrast, a trial of a probiotic containing *S. thermophilus*, *L. acidophilus*, and *B. longum* in another cohort of hemodialysis failed to reduce uremic toxins

and inflammatory markers when compared to placebo [157].

Archaea are unicellular microorganisms that were initially thought to be present only in extreme climates. The archaea present in humans are strict anaerobes, predominantly methanogenic, and use TMA as their substrate for growth. Ramezani et al. screened for the colonization potential and TMAO-lowering efficacy of five methanogenic archaea species in C57BL/6 mice fed with high-choline/TMA-supplemented diet and noted that all five species could colonize the mice and lower plasma TMAO levels [158]. Probiotic use remains an active area of interest for the management of CKD and its complications.

## Symbiotics

Symbiotics refer to a combination of prebiotics and probiotics. Guida et al. compared the use of a symbiotic containing inulin, *Lactobacillus*, and *Bifidobacterium* strains to a placebo in CKD 3 and 4 patients and found lower levels of *p*-cresol in the symbiotic group compared to placebo after 1 month [159]. Another randomized study in CKD 3 and 4 patients over 6 weeks showed a reduction in serum nitrogen levels without significant effect on renal function [160]. Rossi et al. used symbiotics in predialysis patients and found lower levels of *p*-cresol without significant lowering of IS. There was increase in albuminuria in the symbiotic arm without any significant difference in renal outcomes [161]. In hemodialysis patients, increase in stool *Bifidobacterium* counts with subsequent improvement in gastrointestinal symptoms has been reported [162,163].

## Other therapies

Other compounds have also been shown to affect the gut microbiome. Sevelamer, a phosphorus binder, has shown to bind endotoxins and has been associated with reduced endotoxin and CD14 levels but appears to have no significant effects on uremic toxins [164–166]. In small studies, oral adsorbent AST-120, an oral sorbent, adsorbs urea-derived ammonia and has been associated with lower plasma IS levels as well as decreased disruption of intestinal epithelial membrane [167,168]. However, larger randomized trials have not shown convincing benefits except for possible mild decrease in progression to dialysis [169]. E5564, a synthetic analog of lipopolysaccharide, has been shown to reduce adverse effects and inflammation arising from endotoxins by blocking the activity of lipopolysaccharide (LPS) in healthy subjects [170,171]. AT-1001, an inhibitor of paracellular intestinal permeability, has been associated with reduced

intestinal barrier dysfunction, inflammation, and gastrointestinal symptoms in celiac disease patients [172].

### Dietary modifications and fecal transplantation

Several studies have demonstrated the beneficial role of dietary fiber (plant-derived nondigestible carbohydrates) in maintaining gut symbiosis in healthy patients. Fibers increase lactic acid bacteria, such as *Ruminococcus*, *Eubacterium rectale*, and *Roseburia*, and reduce *Clostridium* and *Enterococcus* species [173]. In CKD patients, high dietary fiber consumption has been associated with lower levels of C-reactive protein and lower inflammation and mortality in patients with CKD [54,174]. A study in hemodialysis patients showed that increased dietary fiber intake reduced plasma-free levels of IS and *p*-cresol [175].

There is growing interest on the impact of vegetarian, vegan, and plant-based diets on gut microbiome and overall health, as they are high in dietary fibers as well as polyphenols, which increase the beneficial bacteria *Bifidobacteria* and *Lactobacillus* and provide anti-inflammatory effects and cardiovascular protection [175]. Adherence to plant-based diets has been associated with favorable kidney disease outcomes, but more studies are needed to investigate the connection between plant-based diets, the gut microbiome, and CKD progression [176].

Fecal microbiota transplantation has improved bacterial diversity and demonstrated efficacy against *Clostridium difficile* colitis but no trials have been conducted in CKD [177,178].

### Microbiome engineering

Microbes can be engineered into “smart” living therapeutic agents programed to produce a continuous and inexpensive supply of heterologous molecules of biomedical interest that could be used in the treatment of myriad of diseases [179]. For example, bacterial tryptophanases convert tryptophan to indole, which is then absorbed and modified by the host to produce IS. Devlin et al. found that in the majority of individuals, the genus *Bacteroides* has the most abundant tryptophanases in the gut microbiome. In a series of in vitro and animal studies, they showed that deleting this gene eliminates the production of indole in vitro, and that alteration of gene expression of tryptophanase as well as reduction of *Bacteroides* lower generation of IS [180].

In the intestine, bacterial urease converts host-derived urea to ammonia and carbon dioxide. Shen et al. showed that animals inoculated with altered *Schaedler flora* (a defined consortium of eight bacteria with minimal urease gene content) resulted in a

persistent reduction in fecal urease activity and ammonia production [181].

### Conclusion and future directions

In summary the gut microbiome vastly outnumbers the human genome and has a symbiotic relationship with its host, performing various nutritional, metabolic, and immune functions. An altered bacterial flora is termed dysbiosis. Gut dysbiosis is associated with the degradation of the intestinal membrane, as well as increased intestinal permeability and translocation of gut-derived uremic toxins into the blood. This results in inflammation, CKD progression, and worsening of various metabolic diseases. In CKD, uremia, as well as factors such as constipation and antibiotic use, leads to further dysbiosis and accumulation of uremic toxins. Uremic toxins such as IS and PCS are associated with CKD progression, CVD, bone disease, and inflammatory diseases. Use of prebiotics, probiotics, and symbiotics has been attempted to restore symbiosis of gut flora and has shown inconclusive results. High fiber and plant-based diets may also be beneficial to the gut microbiome, but more research is needed in patients with CKD. Targeted interventions on the gut microbiome may potentially halt the progression of kidney diseases as well as cardiovascular and metabolic diseases.

## Introduction

Protein-energy wasting (PEW) and frailty are complex, overlapping, and interconnected geriatric syndromes (Fig. 12.1). Both are associated with unfavorable outcomes in the chronic kidney disease (CKD) and non-CKD populations and early diagnosis is critical to intervening effectively. Although both PEW and frailty have become more recognized recently, they are underdiagnosed partly due to the lack of a single definition for each and a scarcity of diagnostic tools that can be utilized in clinical practice.

In this chapter, we will focus on assessing the components of the diagnostic criteria of PEW and frailty in CKD patients. The risk factors of these syndromes will also be discussed.

## Assessment for protein-energy wasting

PEW is a state of decreased body reserve of protein and energy [1]. Frailty is one of the geriatric syndromes of poor functional status or physical reserve as a result of worsening multiple organ functions, which leads to poor health consequences [2–4]. Frailty and PEW are interconnected and share several contributing factors, especially among CKD patients (Fig. 12.1).

Methods to assess for and diagnose each condition can help to plan for interventions, improve prognostication, and clarify further research goals.

## Diagnosis of protein-energy wasting

Given the heterogeneity of definitions for PEW, the International Society of Renal Nutrition and Metabolism committee proposed the definitions and criteria for the diagnosis of PEW. Abnormalities of nutrition-related laboratories, body composition, and dietary intake are used for the diagnosis of PEW, with at least three of the four abnormalities needed to diagnose PEW (Table 12.1) [1]. However, protein and energy-wasting may occur separately in the absence of a confirmed diagnosis of PEW [1].

The information and criteria needed to diagnose PEW can mostly be obtained by physical examination and routine laboratory data; however, some criteria are not routinely done in clinical practice limiting the generalizability and adoption of widespread PEW assessments, especially among CKD patients where this information may prove useful for prognostication and counseling regarding possible anticipated outcomes.

Nutrition status can be assessed through both anthropomorphic and nonanthropomorphic measurements, all

FIGURE 12.1 Interconnection between PEW and frailty. CKD, Chronic kidney disease; PEW, protein-energy wasting.

TABLE 12.1 Diagnostic criteria for protein-energy wasting by the International Society of Renal Nutrition and Metabolism [1].

Criteria	Definitions	Comments
1. Nutrition-related laboratory abnormalities	<ul style="list-style-type: none"> <li>Serum albumin &lt;3.8 g/100 mL</li> <li>Serum prealbumin (transthyretin) &lt;30 mg/100 mL (for maintenance dialysis patients only; levels may vary according to GFR level for patients with CKD stages 2–5)</li> <li>Serum cholesterol &lt;100 mg/100 mL</li> </ul>	<ul style="list-style-type: none"> <li>3.8 g/100 mL is the value when albumin is measured by bromocresol green</li> </ul>
2. Decreased body mass	<ul style="list-style-type: none"> <li>BMI &lt;23 kg/m<sup>2</sup></li> <li>Unintentional weight loss over time: 5% over 3 months or 10% over 6 months</li> <li>Total body fat percentage &lt;10%</li> </ul>	
3. Low muscle mass	<ul style="list-style-type: none"> <li>Muscle wasting: reduced muscle mass 5% over 3 months or 10% over 6 months</li> <li>Reduced midarm muscle circumference area (reduction &gt;10% in relation to 50th percentile of reference population)</li> <li>Creatinine appearance</li> </ul>	
4. Poor dietary intake	<ul style="list-style-type: none"> <li>Unintentional or involuntary low DPI &lt;0.80 g/kg/d for at least 2 months for chronic dialysis patients or &lt;0.55 g/kg/d for patients with stage 2–5 CKD</li> <li>Unintentional low DEI &lt;25 kcal/kg/d 1 for at least 2 months</li> </ul>	<ul style="list-style-type: none"> <li>DPI and DEI can be assessed by dietary diaries and interviews, or for protein intake by calculation of nPNA or nPCR as determined by urea kinetic measurements</li> </ul>

BMI, Body mass index; CKD, chronic kidney disease; DEI, dietary energy intake; DPI, dietary protein intake; GFR, glomerular filtration rate; nPCR, normalized protein catabolic rate; nPNA, normalized protein nitrogen appearance.

of which have their strengths and limitations. Routine clinical and laboratory measurements such as body mass measurements and biochemical markers are easily obtained in most clinical settings. However, the common laboratory variables of albumin, prealbumin, creatinine, and cholesterol can be affected by the presence of inflammation or liver disease, necessitating caution when interpreting nutrition status solely based upon these values alone. Other measurements of muscle mass such as computed tomography (CT) scans, creatinine kinetics, and midarm muscle circumference (MAMC)

are not routinely done and may expose patients to unnecessary radiation. Additionally, dietary intake recalls are typically time-consuming and hand-grip measurements rely on specialized instruments not readily available in most clinical settings.

Body composition can also be ascertained directly through dual-energy X-ray absorptiometry (DXA) (Table 12.2). However, while DXA remains the gold standard in body composition measurements, it is labor intensive, invasive, expensive, increases potentially unnecessary radiation exposure, requires specialized

**TABLE 12.2** Direct and indirect methods for body composition measurement for anthropometry to assess nutritional status in chronic kidney disease (CKD) and end-stage kidney disease patients.

	Body composition measurement for anthropometry	
	Direct measurement	Indirect measurement
Methods	<ul style="list-style-type: none"> <li>• Weight</li> <li>• BMI</li> <li>• BIA</li> <li>• NIR</li> <li>• DXA</li> </ul>	<ul style="list-style-type: none"> <li>• Body mass               <ul style="list-style-type: none"> <li>• Weight, BMI</li> <li>• Total body fat percent (SKF, BIA)</li> <li>• Waist circumference</li> <li>• WHR</li> </ul> </li> <li>• Muscle mass               <ul style="list-style-type: none"> <li>• Midarm muscle circumference</li> <li>• Creatinine kinetics</li> <li>• NIR</li> <li>• Abdominal CT scan at the L3 vertebral level</li> </ul> </li> </ul>

equipment not available at all centers, and is potentially influenced by several CKD-related factors such as hydration status. Indirect measurements of body composition can be done in routine clinical practice, including ascertaining body mass, size, shape, and levels of fatness and leanness by measuring height, weight, skinfolds, and circumferences. More technical and precise measurements with bioelectrical impedance analysis (BIA), creatinine kinetics, and near-infrared interactance (NIR) are not as readily available currently, but likely will increase in prevalence with increasing availability and lower cost of these devices in the future (Table 12.2; Fig. 12.2) [5].

## Serum biochemical markers of nutrition

### Serum albumin

Several epidemiological studies have consistently shown the association between low serum albumin and mortality in end-stage kidney disease (ESKD) [6–10] and hospitalizations [5].

There is also a negatively graded association between serum albumin and CKD progression to ESKD in diabetic CKD patients [11]; however, there are several factors that affect serum albumin (Table 12.3).

In addition to poor nutrition intakes such as from uremic symptoms and inadequate dialysis, hypoalbuminemia can result from decreased synthesis, increased utilization, and exogenous losses. Conditions leading to decreased synthesis commonly seen in hemodialysis (HD) patients include protein-calorie malnutrition, inflammation, illness, liver failure, or increase muscle catabolism. Increased utilization can be from an increased fractional catabolic rate. Exogenous albumin loss can be via urine or dialysate. Hypoalbuminemia is common among peritoneal dialysis (PD) patients due to plasma volume expansion [5,13].

Although hypoalbuminemia is associated with poor kidney and mortality outcomes, a recent observational study found that stage 5 CKD patients with low serum albumin and elevated high-sensitive C-reactive protein (hsCRP) had a greater mortality risk than those with low serum albumin levels but normal hsCRP [14]. Therefore hypoalbuminemia may be a marker of inflammation in the uremic milieu potentially clouding the ability to diagnose PEW [15–18].

Since serum albumin is influenced by several nonnutritional factors, especially inflammation, we do not recommend its use in isolation to assess nutritional status. Instead, it should be used as a screening tool or incorporated with other tests to assess nutritional status [5].

### Serum prealbumin (transthyretin)

Serum prealbumin is a protein synthesized by the liver with a more rapid rate of hepatic synthesis and a more reliable catabolic rate than serum albumin [19]. It circulates with a short half-life and is a relatively sensitive marker for altered nutritional status [5,20]. Similar to serum albumin, low prealbumin levels are associated with higher mortality risk and risk of hospitalization in ESKD patients [21].

Prealbumin in ESKD patients has been positively correlated with normalized protein catabolic rate (nPCR), a marker of nutrition and protein intake, and negatively correlated with inflammatory markers such as interleukin 6 [22]. In combination with serum albumin levels, prealbumin levels are a helpful tool to

HD, Hemodialysis; PD, peritoneal dialysis.

discern between true malnutrition versus inflammation-induced reduction in serum albumin [23].

Another limitation to using prealbumin is that it is cleared by the kidneys [5] and its level may vary by estimated glomerular filtration rate [1].

### Normalized protein catabolic rate or normalized protein nitrogen appearance

nPCR, otherwise known as normalized protein nitrogen appearance (nPNA), is used to estimate daily protein intake. In HD patients, nPCR is calculated by comparing pre- and post-HD blood urea nitrogen (BUN) [24,25]. In PD, nPCR is calculated by using urea of the PD fluid and BUN [25].

While serum BUN measurements may provide accurate estimates of nPCR among dialysis patients, the calculations typically underestimates nPCR in patients with a significant amount of residual kidney function (RKF) [26,27]. In patients with RKF or in CKD patients, a 24-hour urine urea collection is typically required to calculate a more accurate nPCR.

Among dialysis patients, research has shown that nPCR is correlated with serum albumin [12] and prealbumin [22]. Additionally, lower levels of nPCR have been associated with a higher risk of mortality, but point estimates for this association are lower than compared to the point estimates for the association between serum albumin and mortality [28].

### Serum cholesterol

Lipid derangements are common among CKD patients and while higher cholesterol levels are typically reflective of a good nutrition status, there are many factors (not the least being the ubiquitous use of statins among this high-risk group) that drive cholesterol levels that have made

this the least reliable method for determining nutritional adequacy among CKD patients. In the absence of other factors, CKD patients generally have higher plasma triglyceride and very-low-density lipoprotein (LDL) cholesterol levels along with lower high-density lipoprotein levels [29,30]. Total-density lipoprotein and LDL cholesterol are generally normal or may decrease [31]. Among patients with nephrotic syndrome, high cholesterol and LDL levels are common [32]. In addition to cholesterol-lowering medication, other conditions such as urinary or gastrointestinal protein losses along with liver disease can affect serum cholesterol levels further limiting its generalizability as a marker of malnutrition [1].

### **Body mass**

The human body comprises both solid mass (musculoskeletal or fat) and liquid mass (intravascular or interstitial fluid). In defining PEW, researchers have separated out two distinct criteria associated with body mass: decreased total body mass and low muscle mass. In clinical practice, weight and body mass index (BMI) are readily available markers of total body mass, but these have their own limitations as we will discuss. Additionally, muscle mass can be more difficult to measure quickly in a clinical setting and we will discuss some potential limitations to this definition in the next section.

### **Body mass index**

BMI is one of the most commonly used biomarkers for body mass and normalizes weight for height [33–35]. While non-CKD patients generally have lower risks of poor outcomes among patients with a normal BMI, CKD and dialysis patients have been noted to have an “obesity paradox,” whereby overweight or obese patients who are metabolically healthy tend to have a lower risk of mortality compared to their normal-weight counterparts [36,37]. Interestingly, overweight and obese patients who are not metabolically healthy do not appear to have this lower risk of mortality [37–39].

The complex interplay between the various mass compartments (solid vs liquid) is nicely demonstrated by a study that found that obese dialysis patients with lower muscle mass (sarcopenia) had a higher risk of death compared to patients who had normal muscle mass [40]. This interplay is not readily ascertained just by looking at BMI alone. Researchers have begun to appreciate that body composition is a more important prognostic marker than assessment of BMI alone. Furthermore, nuances of body composition that have been associated with PEW and malnutrition are not completely captured by a holistic BMI approach, especially the ratio of fat, muscle, and visceral adiposity [5].

In addition to the limitations addressed previously when looking at BMI, colleagues around the world should also be mindful of population-specific BMI cutoffs to

determine PEW, as these may vary by ethnicity. While BMI <23 kg/m<sup>2</sup> meets one of the criteria for PEW, Asian ethnicities typically have a lower population-averaged BMI and lower BMI values under 23 kg/m<sup>2</sup> may not necessarily be reflective of PEW [41,42].

Due to the limitations of using BMI as a marker of PEW and malnutrition, the 2020 KDOQI clinical practice guideline for nutrition in CKD recommends measuring BMI periodically, but not using BMI and waist circumference (WC) for nutrition screening in polycystic kidney disease (PKD) patients [5].

Nevertheless, dynamic changes in BMI can be indicative as a risk factor for PEW, especially unintentional weight loss of greater than 5% or 10% over 3 or 6 months, respectively, may be a sign of PEW [1,5].

To monitor overall nutrition status, combined measurements of BMI and body composition are recommended at the first and subsequent visits at least every 6 months in mild–moderate CKD with increasing frequency in severe CKD given the risk of decline is typically much faster among patients with the latter stages of CKD [5].

With respect to individual components of the body, researchers have shown a significant association with greater mortality among patients with a total body fat (TBF) percentage less than 10 in nonmuscular individuals [43–45]. In addition, muscle mass loss is also a marker of PEW [46,47]. As such, assessing only the total solid component of body composition may not highlight these important differences and it is the ratio of fat, muscle, and liquid component that may be a more helpful prognostic marker of poor outcomes among CKD patients.

Lastly, there are several definitions of optimal weight among CKD patients, all of which have their strengths and weaknesses. The ideal body weight (IBW) as measured by the Hamwi method is the weight associated with the lowest mortality given patients demographic but has not been validated among CKD patients [48].

Standard body weight is derived from the Second National Health and Nutrition Examination Survey II using the median body weight of average Americans from 1976 to 1980 for height, age, sex, and frame size. Unlike the IBW, standard body weight provides just individual weight and its associations with morbidity and mortality have not been studied [25]. Additionally, the body composition of Americans has changed over the last 40 years and this definition may no longer be suitable to the modern US population, nor can it be generalizable to populations outside the United States.

Adjusted body weight is another possible definition of IBW but it is also not validated among CKD patients. This construct assumes that 25% of the excess body weight (adipose tissue) in obese patients is

metabolically active tissue, which may not necessarily be true among CKD patients [49].

Among ESKD patients, desirable body weight and edema-free body weight have been used as potential ideals of “dry weight.” Desirable body weight is postdialysis weight based on BMI. The lower 50th percentile of patients for desirable body weight has been associated with a higher risk of mortality among dialysis patients [34]. Similarly, edema-free body weight is an estimated dry weight [50], which is the lowest postdialysis weight after a gradual and persistent lowering of a patient’s postdialysis target weight until one has achieved a weight with minimal signs or symptoms of hypo- or hypervolemia [51].

Unfortunately, this is not yet a validated and standard optimal body weight measurement among CKD patients and further research is needed to come up with a weight target that is reasonable, is easy to calculate, and is associated with a lower risk of CKD progression and mortality. In addition, we advocate for enhancing the use of body composition measurements to improve our prognostic information as well as our understanding of the complex interplay of the various body components.

### Total body fat percentage

While DXA is the gold-standard method of assessing TBF percentage, there are various other potentially easier field methods that have been studied and used as a surrogate marker. TBF percentage of less than 10% is one of the criteria for the diagnosis of PEW [1].

Skinfold thickness (SKF) is one of the established methods to assess body fat (BF) among HD patients that is both simple and inexpensive [5,52]. SKF can be measured from different body sites, including biceps, triceps, pectoral, subscapular, mid axilla, abdomen, suprailiac, and quadriceps. SKF can be converted to BF percentage by several formulae based on age and gender [53–55]. In a study assessing parameters associated with malnutrition, a lower biceps skinfold as measured by skinfold calipers was associated with a worse malnutrition score among ESKD patients [56].

Additionally, triceps skinfold (TSF), NIR, and BIA have yielded consistent estimates of TBF percentage among HD patients compared with other index tests [57,58]. The BIA devices used to measure these parameters are easier to use, more portable, and potentially can be utilized effectively within a clinical setting. However, in other studies using the Segal [59] and Lukaski methods for estimating BF [60], the BIA equations overestimated TBF percentage [58] and there appears to be gender-specific variability in the assessment of BF [52]. Because of these discrepancies, SKF may be a better a preferred method for BF assessment among HD patients [61]. Among CKD patients, SKF appears to

have good agreement with DXA results so utilization of SKF may be an appropriate surrogate to measure BF among mild-to-advanced CKD patients [62].

While SKF is relatively quick and easy to obtain clinically, it has its limitations. Morbidly obese patients that cannot accommodate skinfold calipers along with patients with very low fat percentage may provide inaccurate measurements [5].

While obtaining a single measurement of BF may be helpful in point prognostication, longitudinal measurements likely have higher accuracy over time and changes can be used to track interventions aimed at lowering BF and increase muscle mass over [5].

In addition to SKF, regional adiposity measurements can also be indicative of nutritional status. WC is measured over the unclothed abdomen, just above the iliac crest, and is an indirect measurement of body composition. Alternatively, WC can be measured at the level of the umbilicus. It indicates abdominal fat deposition or abdominal obesity and can reflect the increased cardiovascular risk associated with excessive visceral fat [63,64]. In addition to WC, hip circumference measured at the widest diameter around the buttocks and the waist-to-hip ratio (WHR) has also been associated with cardiovascular outcomes [65]. Among PD patients, WC remains a reliable marker of abdominal adiposity despite several other factors contributing to WC, including abdominal distension from PD fluid, the presence of the PD catheter, and the presence of abdominal hernias [66].

Interestingly, WC predicts the risk of poor outcomes better in normal and overweight compared to obese patients, particularly whose  $BMI \geq 35 \text{ kg/m}^2$ . Regardless, there remains a strong correlation between WC, WHR, and cardiovascular risk among CKD patients [67] and mortality in maintenance HD (MHD) patients [68].

### Muscle mass

Muscle wasting is one of the most important in the diagnosis of PEW. Decreased muscle mass of 5% or 10% over 3 or 6 months, respectively, meet one of PEW’s diagnostic criteria. However, it is difficult to directly measure muscle mass loss [69], and there is a lack of clinical tools for accurately assessing accelerated muscle protein catabolism [70]. Therefore several biomarkers have been proposed as surrogate markers to assessing muscle mass loss in clinical practice.

### Serum creatinine

Serum creatinine has long been utilized for indirectly assessing muscle mass, although it lacks accuracy and reproducibility [1] and can be affected by several factors, especially kidney disease, limiting its use in the majority of clinical settings (Table 12.4) [71]. A more accurate measurement of muscle mass has been derived

TABLE 12.4 Common factors affecting serum creatinine [71].

Factors affecting serum creatinine	Common conditions	Mechanism
<b>Increased serum creatinine</b>		
Laboratory interference	<ul style="list-style-type: none"> <li>• Ketosis</li> <li>• Some cephalosporins</li> <li>• Flucytosine</li> </ul>	<ul style="list-style-type: none"> <li>• Ketones react in the picric acid assay for creatinine</li> <li>• React in the picric acid assay for creatinine</li> <li>• React in the iminohydrolase assays for creatinine</li> </ul>

<b>Decreased serum creatinine</b>		
Diet	<ul style="list-style-type: none"> <li>• Restriction of dietary protein</li> </ul>	<ul style="list-style-type: none"> <li>• Decreased creatinine generation</li> </ul>
Skeletal muscle	<ul style="list-style-type: none"> <li>• Low muscle mass or muscle loss</li> </ul>	<ul style="list-style-type: none"> <li>• Decrease in muscle creatinine generation</li> </ul>
Physical activity	<ul style="list-style-type: none"> <li>• Vigorous prolonged exercise</li> </ul>	<ul style="list-style-type: none"> <li>• May increase muscle creatinine generation</li> </ul>

from creatinine kinetics, which assesses the total excretion of creatinine in the urine per day assuming that creatinine production is proportional to the amount of muscle mass that remains constant. Creatinine kinetics has been correlated with muscle mass measured by other methods such as CT scan or anthropometric measurements [72] and has been recommended by the 2020 KDOQI guidelines as a method to estimate muscle mass among CKD patients [5].

Obtaining creatinine kinetics requires a 24-hour urine collection, but again this measurement is also affected by other issues, including protein intake [62,71]. Among dialysis patients, urine collections may not be feasible especially among those who are oliguric or anuric. Assessing creatinine kinetics through predialysis serum creatinine levels, interdialytic changes in serum creatinine, and weekly creatinine clearance has provided similar markers of muscle mass that have been associated with mortality [28,72,73]. Similar to MHD patients, creatinine kinetics and serum creatinine have been associated with body composition, muscle mass, and mortality among PD patients [74–76].

In addition to creatinine, creatine kinase levels can be utilized as another surrogate marker of muscle mass with moderate reproducibility. It has been correlated with BF ( $r = 0.47$ ) and fat-free mass (FFM) ( $r = 0.57$ ) from DXA [62].

### Midarm muscle circumference

MAMC is a marker of lean muscle mass. Among dialysis patients, midarm circumference (MAC) and

MAMC are associated with nutritional markers, including serum albumin [77] and the 7-point Subjective Global Assessment (SGA) score, a standard method for diagnosing malnutrition [78]. MAMC is calculated from the following formula:  $MAMC = MAC - (3.14 \times TSF \text{ thickness})$ . Decreased MAMC area  $>10\%$  with the 50th percentile of the reference population meets one of the criteria for PEW [1].

### Bioelectrical impedance analysis

BIA is a common technique used to estimate total body water, and from total weight, one is typically able to calculate fat and muscle mass [79]. Different types of BIA can be used to assess different components of body composition such as hydration status [80], muscle mass [81], and percent BF [82]. Body composition as measured by BIA has been associated with other nutritional measures [83,84], mortality [85], and has also been shown to be associated with mortality [43] in MHD patients.

Compared to DXA, fat mass (FM) ascertained through BIA tended to overestimate FM while underestimating FFM in MHD patients [86]. However, BIA appears to be a robust tool for measuring and monitoring TBF and lean body mass in HD patients compared with DXA. In the same study, researchers found that there was interestingly less correlation between DXA and BIA when assessing bone mineral content suggesting that BIA is likely a tool for assessing soft tissue [87].

Studies have also looked at BIA as a tool for predicting total body protein, specifically calculation of a body protein index (BPI) score that normalizes protein mass

for patient height. While correlation levels were high among male HD patients, the score was less accurate among female participants limiting the generalizability of the score to a wider population. Additionally, the BPI score calculated through BIA was less accurate among PD patients [88].

While the BIA is a powerful surrogate for muscle mass, it appears to be less useful among PD patients. It is possible that fluid shifts among PD patients limit its use in this population and studies have shown a variation in agreement between BIA and DXA for assessing fat and FFM [89].

Given the effect of hydration status on assessing body composition with BIA, it has been suggested that testing should be done at least 30 minutes after the end of dialysis on a nonconducting surface to allow for redistribution of body fluids. Unfortunately, there continues to be a lack of evidence to support BIA use among CKD and PD patients.

### Computed tomography scan

The abovementioned methods of assessing muscle mass can provide a surrogate marker of the muscle quantity. However, hydration status can interfere with these anthropometric and DXA measurements limiting their use, particularly among CKD and ESKD patients where volume overload is a frequent issue. While researchers have assumed a uniform hydration of 73% of lean body mass, this assumption can both overestimate or underestimate lean body mass quantification depending upon hydration status [90,91].

As surrogate measures have their limitations, CT scanning of muscle mass has become the gold standard for the detection of muscle wasting in clinical trials due to its high precision, accuracy, and reliability without interference from hydration status [92,93]. Even among oncologic patients where muscle wasting is also frequent, CT measurements of muscle mass appear to correlate highly with fat-free and appendicular skeletal muscle (SKM) mass [94]. In addition to muscle quantity, a CT scan can also assess muscle quality by its ability to detect the fatty infiltration in the muscle, which is not available by DXA [95]. Both CT and MRI have been shown to have good correlation when assessing total body SKM volume with the former being faster and typically less expensive [96].

There are various methods of CT measurements, including single abdominal CT imaging at the third lumbar vertebra level as well as complete CT imaging that utilizes a higher radiation dose. However, studies have shown that while prediction equations to calculate whole-body FFM, whole-body FM, and appendicular skeletal mass using CT scanning correlate well with DXA scanning measurements, single abdominal CT imaging does not provide as accurate a measurement

and is likely not a sufficient surrogate for DXA when assessing body composition [97].

In stages 3–5 CKD patients, muscle mass evaluated by a CT scan showed the highest correlation with the MAMC followed by the Baumgartner predictive equation of SKM mass in both men and women [95].

While CT scans have yielded significant power to be able to measure muscle mass, researchers have yet to establish definitions for muscle depletion based upon these readings; hence, further studies are required to validate the clinical utility of the CT scan for assessing SKM mass in the CKD population [95].

### Dietary intake

Both under- and overnutrition affect a patient's health status with low protein and/or energy intake potentially heralding PEW. Determining reliable methods to assess protein and energy intake has been challenging. Current reference standards for assessing dietary intake have food records or food diaries [5]. However, the addition of laboratory data not subject to recall bias, such as a 24-hour urine collection for urinary urea nitrogen, may improve the accuracy of dietary intake assessment.

### Dietary protein intake

Patients' symptoms are currently one of the most important parts to improving patient-centered care in the CKD and ESKD (end-stage kidney disease) population [98,99]. Anorexia leading to unintentional low dietary protein intake (DPI) is evidence of PEW and predicts poor outcomes [100,101]. When assessing DPI, recommendations for ESKD patients requiring a higher daily protein intake are opposite to CKD patients who are recommended to be on a low-protein diet [5]. Reconciling these differences in the definition of PEW is challenging, but researchers have suggested that *unintentional* or involuntary low DPI of less than 0.6 g/kg/d for stages 2–5 CKD patients is one criterion for PEW [1].

DPI can be assessed by dietary records/diaries, interviews, food frequency questionnaires, or by the nPCR as determined by urea kinetic measurements [1,5].

Although food records/diaries are usually reliable and correlated with reference standards, its accuracy is mostly limited by recall bias. Training and instruction on how to do an adequate food recall, as well as at least 7 days of food records, has been shown to improve the accuracy of food records [102–104].

In addition to food records/diaries, a 24-hour urine collection for urinary urea nitrogen to assess protein intake is an underutilized but reliable method for assessing daily protein intake. Unfortunately, use is limited by patient convenience and ability to correctly collect the urine specimen. Done properly though, calculating the nPCR from a 24-hour urine collection is

highly correlated with the DPI when using dietary recall as a reference standard among CKD patients [105–107]. However, overestimation can occur if protein intake is less than 1 g/kg/d or underestimation can occur if protein intake is greater than 1 g/kg/d when using the nPCR method [106].

Among PD patients, PNA normalized to desired body weight correlated well with BUN levels as a marker of DPI [107].

### Dietary energy intake

Compared to DPI, dietary energy intake (DEI) encompasses a wider range of foods that contribute to a patient's energy intake, including fats and carbohydrates. When assessing for PEW, researchers have found that unintentional low DEI of 25 kcal/kg/d for at least 2 months in CKD and ESKD patients has been associated with PEW [1]. Similar to DPI, DEI can be assessed by food records/diaries and interviews [1].

While assessing energy intake through food records is usually reasonable, this method is also limited by recall bias and also tends to underestimate the energy intake [108]. In addition, among CKD and PD patients, energy intake recall methods tend to underestimate energy intake when compared to values obtained from resting energy expenditure (REE) using indirect calorimetry with the underestimation being most apparent among overweight patients [109,110].

Among HD patients, food frequency questionnaires by using the Block Brief 2000 food frequency questionnaire tended to underestimate energy intake compared to a 3-day food diary record, but simple calibration equations could be used to correct for systematic biases [111].

### Comprehensive nutritional assessment

As there are several tools to diagnose and screen for PEW all having their own limitations, we recommend using a combination of various tools as a composite of nutritional indices to provide a comprehensive nutritional assessment. These assessments should be helpful in guiding clinicians to not only identify the risk factors and diagnose PEW earlier, but also allowing for earlier initiation of interventions and monitoring of clinical outcomes.

A comprehensive nutritional assessment involves medical and psychosocial histories, clinical symptoms and signs, a dietary intake assessment, anthropometric measurements, and measurement of biomarkers [5].

### Composite nutritional indices

#### Screening for protein-energy wasting

Many tools can be utilized to diagnose PEW; however, early detection by screening CKD patients,

particularly who are at risk for PEW (Fig. 12.3), can provide opportunities to initiate a *chain of nutrition care* to mitigate the outcomes of malnutrition and wasting or severe PEW in sarcopenic elderly CKD patients (Fig. 12.4).

The 2020 KDOQI guideline on nutrition in CKD suggests performing routine nutrition screening in stages 3–5 CKD patients twice a year to identify patients who have an increased risk of PEW. There is no single tool that can identify at-risk CKD patients [5] and several tools should likely be incorporated to determine signs of PEW. In addition, a multidisciplinary team, including registered dietitians, is critical to preventing, treating, and mitigating the outcomes of PEW.

Several screening tools comprising composite nutritional indices are shown in Table 12.5 [5].

#### Assessment tools for PEW

**Subjective Global Assessment of nutrition** The SGA of nutrition assesses nutritional status based upon features of the clinical history and physical examination (weight changes, eating habits, gastrointestinal symptoms, functional activity, and comorbid conditions) and was initially validated among patients undergoing gastrointestinal surgery in 1987. The SGA has been validated among ESKD patients. Among dialysis patients, a modified SGA score was associated with extracellular weight-to-body weight ratio using bioimpedance spectroscopy measurements [112]. Interestingly, one study did not show any correlation between SGA scores and dietary protein and energy intake in either CKD or ESKD patients [113].

Additionally, a higher SGA score was also associated with mortality among both HD and PD patients [28,76,114–116]. The SGA has widely been accepted as a reasonable tool for assessing nutritional status among HD patients but has not yet been accepted as diagnostic criteria for PEW among CKD patients [117,118].

**Malnutrition–inflammation score** The malnutrition–inflammation score (MIS), also known as the Kalantar Score, is a 30-point score assessing components of nutritional and inflammation among HD patients. MIS was found to have good agreement with SGA (subjective global assessment) [119] and strongly correlated with modified quantitative SGA score [120] in MHD patients. The MIS has also been associated with increased mortality [21,28,114,119], cardiovascular events [28], and hospitalizations [21] among HD patients.

Although the composite nutritional indices can identify poor nutritional states such as malnutrition and predict clinical outcomes in CKD and ESKD patients, their utility to detect PEW remains uncertain [5].

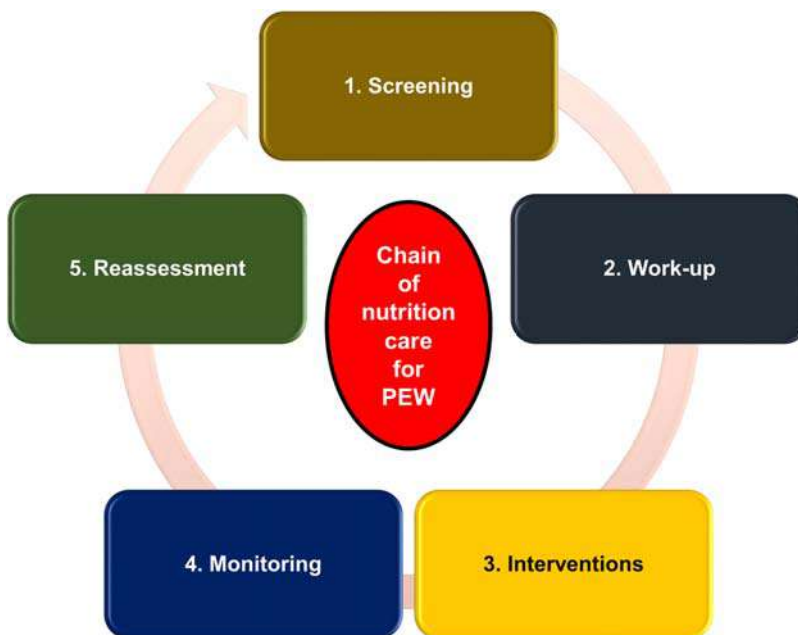

FIGURE 12.4 A chain of nutrition care for PEW. *PEW*, Protein-energy wasting.

### Assessment for frailty

Frailty is a clinical state marked by a loss of resilience and diminished capacity to respond to health stressors and has been widely recognized as one of the

important geriatric syndromes leading to poor clinical outcomes, including increased risks of falls [2,121], worsening kidney function [122], mortality, and hospitalizations [123–128]. In addition, frailty has been associated with higher cost of care compared to nonfrail

MIS, Malnutrition–inflammation score; SGA, Subjective Global Assessment.

individuals, primarily due to higher inpatient costs and higher costs near the end of life.

The prevalence of frailty in the community-dwelling older adult population is approximately 11% [129]. In the kidney disease population this prevalence is even higher with studies suggesting between 30% and 73% of ESKD patients being frail [123,124].

While there exist several tools for screening, diagnosing, and determining the severity of frailty, researchers have yet to agree on a standardized definition, likely due to the multifaceted nature of frailty [130]. Operationalizing frailty has been largely divided into three different methods: (1) the Frailty Phenotype (FP), a physical construct of frailty, (2) the Frailty Index (FI), a deficit model of frailty, and (3) the Frailty Score, a subjective construct of frailty. Each definition has its own advantages and disadvantages, but all have been linked to poor outcomes among those defined as frail.

Recent studies have shown reversibility of frailty, even among dialysis patients who are traditionally thought of as having a high degree of comorbid conditions. This reversibility suggests that prompt identification of frailty in CKD and ESKD patients may mitigate some of the poor outcomes associated with frailty.

## Diagnosis of frailty

The FP is the most used frailty definition among researchers studying CKD and ESKD populations, but notably, other definitions are also associated with poor

outcomes. Because the FP is defined by physical characteristics, including grip strength and gait speed, assessment of this phenotype in clinical practice is limited by availability of staff to perform this comprehensive assessment. On the other hand, the FI and Frailty Score may be easily obtained through chart review, EMR (electronic medical record) analysis, or even a cursory assessment as part of normal clinical practice.

Despite significant advances in the assessment of frailty among dialysis patients and our understanding that frailty makes patients vulnerable to poor outcomes, researchers still lack consensus on a single, easily adapted operational definition of frailty that would allow improved quantification and adequate comparison between studies. Perhaps widespread adoption of frailty assessment may not occur until a simpler construct is achieved. Alternatively, expansion of electronic health records and development of advanced data mining strategies might facilitate collection of frailty markers from various sources, including within dialysis and outpatient nephrology clinics [131]. Identification of these high-risk patients may allow tailored interventions, provide more accurate prognostic information, and improve provider-to-patient discussions on the risks and benefits of interventions such as dialysis.

## Fried phenotype model of frailty

The physical construct of frailty was developed and validated by Fried et al. in a cohort of community-dwelling elderly in a study published in 2001 [2]. Individuals were considered frail if three of five major physical components of frailty were identified: shrinking or weight loss, weakness, poor endurance and energy, slowness, and low physical activity level (Table 12.6). Fried's original frailty construct has been

TABLE 12.6 Fried's Frailty Phenotype [2].

Phenotype	Measurement	Criteria
1. Shrinking	• Self-report/weight measurement	• Lost 10 lb (4.5 kg) in the past year
2. Weakness	• Dynamometer for grip strength	• Weakest 20% by gender and body mass index
3. Poor endurance and energy	• Self-report: "trouble getting going"	
4. Slowness	• Walking speed by timing a 15-ft or 5-m walk	• Slowest 20% by gender and height
5. Low physical activity level	• Self-report: number of calories expended	• Lowest 20% • Males: 383 kcal/week • Females: 270 kcal/week

See also text and Table 12.10 for the Fried criteria for Frailty Phenotype.

validated in other elderly populations as well as the CKD and dialysis populations. So far, the Fried phenotype has been the most widely used frailty construct among researchers [131].

### Shrinking

Shrinking is diagnosed when either unintentional weight loss in the prior year of greater than 10 lb or greater than 5% of body weight [2]. This criterion is typically a reflection of malnutrition and/or inflammatory processes ongoing with the body leading to significant weight loss. Inflammatory processes such as CKD, cancer, chronic infection, heart failure, rheumatoid arthritis, and chronic obstructive pulmonary disease can lead to PEW and a hypercatabolic state and its associated weight loss if energy intake dips below energy expenditure [132].

In addition, weight loss needs to be interpreted with caution since some conditions in CKD patients can decrease weight abruptly such as limb amputations and aggressive volume correction in hypervolemic patients, both common among patients with CKD.

### Weakness

The weakness criterion is assessed by grip strength. In Fried's FP, weakness is diagnosed when grip strength is in the lowest peer quintile and is adjusted for gender and BMI. Multiple measurements are obtained from both hands with the highest value typically being recorded for frailty assessment.

Although grip strength is a simple test done using a dynamometer, this device is not widely available in clinical practice. Staff training to properly perform the test and interpret the results is required. In addition, grip strength testing is limited in those with amputations or debilitation conditions such as a history of stroke or neurological disorder preventing full hand and arm functioning.

### Poor endurance and energy

The poor endurance and energy criterion reflects the psychosocial aspect of frailty. Fried and colleagues utilized two questions regarding self-reported inability to get going from the Center for Epidemiological Studies Depression scale to define this criterion [133]. A positive response to these questions has been associated with the stage of exercise reached in graded exercise testing, has been used as an indicator of maximal oxygen consumption [134], and has also been used as a predictor of cardiovascular disease [135].

### Slowness

The slowness criterion was defined by measuring walking speed over 15 ft adjusted for gender and weight. Patients in the slowest quintile were considered

as meeting the slowness criterion for frailty. Gait speed remains one of the easiest and fastest methods for determining functional status among both CKD and dialysis patients, including during the prekidney transplant assessment. This criterion is, however, limited among those unable to walk such as amputees, those who are wheelchair bound, patients with severe visual impairment hindering their ability to walk, or patients with neurological deficits preventing ambulation. In these cases, patients are usually deemed to have met the slowness criterion but there are several examples of spinal cord injury patients who maintain excellent functional status without meeting compete frailty criteria despite the inability to walk.

### Low physical activity level

This is a self-reported number of calories expended using a modified Minnesota Leisure Time Physical Activity questionnaire. The presence of low physical activity occurs at the lowest quintile for each gender (383 kcal/week in man and 270 kcal/week in a woman). This criterion has also been associated with coronary heart disease risk factors and subclinical disease among patients 65 years and older in the Cardiovascular Health Study [136].

### *Cumulative deficit model of frailty or the frailty index*

There are various frailty indices that have been used to define frailty. While each differs based upon the number and type of variables, all are similar in that sum up various "deficits" and the accumulation of sufficient "deficits" then defines frailty. The "deficits" include signs, symptoms, comorbid conditions, functional impairments, and laboratory deficits that are thought to be associated with frailty. Each component typically has some correlation with the standardized comprehensive geriatric assessment that is typically used to assess an elderly patient's cognitive status, mood and motivation, communication, mobility, balance, bowel function, bladder function, activities of daily living (ADL) and instrumental ADLs, nutrition, and social resources. For example, Rockwood and colleagues developed a frailty model that included 70 different variables across a range of medical conditions, psychological conditions, and functional impairments [137] (Table 12.7). In this example the accumulation of 25% of these "deficits" defines one as being frail [138].

Frailty as defined by these various frailty indices has been associated with mortality, disease progression, hospitalization, and health-care resource utilization [139]. Unlike the FP, these frailty indices include some clinical measures that can be easily obtained from electronic medical records and laboratory data and, hence, may be a viable option for clinical settings

**TABLE 12.7** Cumulative deficit model of frailty or the Frailty Index with 70 clinical components used in the Canadian Study of Health and Aging [137].

• Changes in everyday activities	• Problems going out alone	• Depression (clinical impression)	• Postural tremor	• Myocardial infarction
• Head and neck problems	• Impaired mobility	• Sleep changes	• Intention tremor	• Arrhythmia
• Poor muscle tone in neck	• Musculoskeletal problems	• Restlessness	• History of Parkinson's disease	• Congestive heart failure
• Bradykinesia, facial	• Bradykinesia of the limbs	• Memory changes	• Family history of degenerative disease	• Lung problems
• Problems getting dressed	• Poor muscle tone in limbs	• Short-term memory impairment	• Seizures, partial complex	• Respiratory problems
• Problems with bathing	• Poor limb coordination	• Long-term memory impairment	• Seizures, generalized	• History of thyroid disease
• Problems carrying out personal grooming	• Poor coordination, trunk	• Changes in general mental functioning	• Syncope or blackouts	• Thyroid problems
• Urinary incontinence	• Poor standing posture	• Onset of cognitive symptoms	• Headache	• Skin problems
• Toileting problems	• Irregular gait pattern	• Clouding or delirium	• Cerebrovascular problems	• Malignant disease
• Bulk difficulties	• Falls	• Paranoid features	• History of stroke	• Breast problems
• Rectal problems	• Mood problems	• History relevant to cognitive impairment or loss	• History of diabetes mellitus	• Abdominal problems
• Gastrointestinal problems	• Feeling sad, blue, depressed	• Family history relevant to cognitive impairment or loss	• Arterial hypertension	• Presence of snout reflex
• Problems cooking	• History of depressed mood	• Impaired vibration	• Peripheral pulses	• Presence of the palmomental reflex
• Sucking problems	• Tiredness all the time	• Tremor at rest	• Cardiac problems	• Other medical history

in which physical frailty models cannot be obtained in a reasonable time.

Many frailty indices require at least 30 items of health information for its calculation, which may be challenging to obtain quickly despite a robust clinical electronic medical record. However, researchers have found that an electronic FI can potentially be generated from primary health-care electronic medical records and frailty defined in this way has also been associated mortality, hospitalization, and nursing home admission [140].

### **Clinical Frailty Scale**

Unlike the FP and the various frailty indices, the Frailty Scale is a subjective assessment based upon clinical judgment. It originally contained seven severity levels that corresponded to seven descriptors for levels of frailty [137]. The 7-point scale was then modified to a 9-point scale with the highest point levels

reserved for terminally ill patients with less than a 6-month life expectancy (Table 12.8) [141].

While the Frailty Scale can be rapidly administered, the subjective nature of this frailty construct may lead to a wide variation among providers making this the least precise method of determining frailty. However, there have been several studies to date suggesting that even frailty based upon a subjective scale can be associated with poor outcomes (Table 12.9) [137,142–144].

Table 12.10 summarizes features of validated frailty measurement, including the FP, the FI (FI of Accumulated Deficits and FI-CGS), and the Frailty Score (Clinical Frailty Scale) [2,137,138,141,145].

### **Screening for frailty**

Screening for frailty is not yet routinely done in clinical practice. Researchers have postulated that the

**TABLE 12.8** 7- and 9-Point Clinical Frailty Scale from the Canadian Study of Health and Aging.

	<b>7-point Clinical Frailty Scale [137]</b>	<b>9-point Clinical Frailty Scale [141]</b>
1. Very fit	Robust, active, energetic, well-motivated and fit; these people commonly exercise regularly and are in the most fit group for their age	Robust, active, energetic, well-motivated, and fit. Commonly exercise regularly
2. Well	Without active disease, but less fit than people in category 1	Without active disease but less fit than category 1
3. Well	With treated comorbid disease—disease symptoms are well controlled compared with those in category 4	Disease symptoms are well controlled compared with those in category 4
4. Apparently vulnerable	Although not frankly dependent, these people commonly complain of being “slowed up” or have disease symptoms	Although not frankly dependent, commonly complain of being slowed up or have disease symptoms
5. Mildly frail	With limited dependence on others for IADL	Limited dependence on others for IADLs
6. Moderately frail	Help is needed with both instrumental and non-IADL	Help is needed with BADLs and IADLs
7. Severely frail	Completely dependent on others for the activities of daily living, or terminally ill	Completely dependent for all BADLs and IADLs
8. Very severely frail		Completely dependent, approaching the end of life. Could not recover from even a minor illness
9. Terminally ill		Life expectancy <6 months but not otherwise frail

*BADLs*, Basic activities of daily living, including feeding, bathing, dressing, toileting, ambulation; *IADLs*, instrumental activities of daily living, including banking, transportation, cooking, cleaning, medication management, shopping.

reason for this lack of assessment is multifactorial. First, clinicians typically have only a cursory understanding of frailty and its components. Second, there is no current standardized method for assessing frailty. Third, assessment of the FP requires specialized equipment and time, neither of which are found in abundance in a typical CKD or primary care clinic. Last, most electronic medical records lack the capability of a sufficiently thorough automatic chart review to make a rapid determination of frailty based upon a FI.

**TABLE 12.9** Clinical Frailty Scale (CFS) and clinical outcomes in different population.

	<b>Population</b>	<b>Clinical outcomes associated with the CFS scores</b>
Rockwood et al. [137]	• General	• An increased risk of death [HR 1.30 (95% CI 1.27–1.33)] and institutionalization [HR 1.46 (95% CI 1.39–1.53)]
Alfaadhel et al. [142]	• At dialysis initiation	• Mortality
Baggett et al. [143]	• Predialysis	• Mortality
Iyasere et al. [144]	• Older patients on assisted peritoneal dialysis and hemodialysis	• Worse health-related quality-of-life scores

CI, Confidence interval; HR, hazard ratio.

However, given the advances in our understanding of frailty as well its associations with poor outcomes, regardless of the method by which it is defined, many researchers are seeing the benefits of obtaining an additional prognostic factor when discussing treatment goals, especially treatments that require an ongoing lifelong commitment such as dialysis. Keeping in mind that frailty can also potentially be reversed, there are calls for early initial and subsequent screenings for frailty. Early identification can lead to early intervention while a worsening in frailty score can herald poor outcomes and provide an objective measure from which to discuss possible transitions of care (e.g., decremental dialysis regimens and/or hospice).

## Treatment of frailty

While there are currently no established treatments for frailty, much research has gone into potentially increasing strength training and exercise capacity to reduce or improve frailty. In addition, studies assessing depression screening and improvement in depression scores have been potentially associated with improvements in frailty. Studies shown such breadth of interventions can potentially change a patient's frailty status show how frailty is not only defined by a physical measurement and muscle mass but also encompasses a psychosocial component. Future research into the pathophysiological basis of frailty may lead to new avenues through which we can potentially decrease the incidence and prevalence of frailty and ultimately mitigate poor outcomes among our patients.

**TABLE 12.10** Features of validated frailty measurement, including Frailty Phenotype, Frailty Index of Accumulated Deficits (FI-CD), FI of Comprehensive Geriatric Assessment, and Clinical Frailty Scale (CFS) [2,137,138,141,145].

## Risk factors of protein-energy wasting and frailty

### Risk factors of protein-energy wasting

In CKD and ESKD, risk factors of PEW include those related and unrelated to CKD (Fig. 12.3). In general, these include conditions that lead to an increased loss of protein or energy (e.g., catabolic conditions, inflammation, and stress) and/or a decreased intake of protein or energy (i.e., inadequate nutrient intake). The factors specifically related to CKD are a chronic inflammatory milieu from CKD itself, anemia, acidosis, decreased levels of or resistance to anabolic hormones [e.g., insulin, growth hormone, and insulin-like growth factor 1 (IGF-1)], and increased levels of catabolic hormones (e.g., parathyroid hormone and glucagon) [146].

#### Increased loss of protein or energy

##### Chronic kidney disease–related factors

**Increased protein loss** Proteinuria, particularly in when in the nephrotic range ( $>3.5$  g/day), increases the risk of protein loss. In addition, while most proteins are retained with HD, smaller sized proteins may

be dialyzable potentially contributing to increased protein loss [146]. Interestingly, patients with nephrotic range proteinuria may improve their proteinuria levels as residual renal function continues to decline [147].

**Increased proteolysis** Proteolysis may develop more readily in the acidic environment typically found among CKD and ESKD patients due to a decrease in proton secretion and bicarbonate regeneration [148]. Correction of metabolic acidosis may slow progression of CKD and subsequently improve nutritional status [149], decrease protein degradation and amino acid oxidation [150], decrease whole-body protein degradation in MHD patients [151], and improve acid–base status and nutrition in CAPD (continuous ambulatory peritoneal dialysis) patients [152]. While correction of acidosis has been associated with beneficial outcomes, the role of bicarbonate supplementation on improving muscle mass in HD patients with PEW remains unclear [153].

**Increased protein or energy utilization** Hypercatabolic states such as those found in CKD and ESKD patients can potentially increase REE by 10%–20% and subsequently lead to PEW [154]. The hypercatabolic state is

typically due to underlying inflammation and high proinflammatory cytokine levels and oxidative stressors that ultimately lead to an increased energy expenditure. Despite this increase in REE, net energy expenditure may decrease among these patients due to a more sedentary lifestyle and a decrease in physical activities leading to weight gain and sarcopenic obesity [155,156]. Among those who are obese, high levels of adipose tissue lead to an increase cytokine and CRP levels further exacerbating sarcopenic obesity [157,158].

In some patients with poor baseline energy expenditure, the hypercatabolic states in CKD and ESKD ultimately lead to malnutrition, weight loss, and PEW.

### Dialysis-related factors

**Increased protein loss** Protein losses through dialysis are not negligible and can be as high as 4–8 g/day among both peritoneal and HD patients [159]. For PD patients, high transporters may even have a higher effluent protein loss [160–163]. In addition to the protein loss in the dialysate, a reduction in protein synthesis can also lead to lower protein levels and subsequent PEW [164,165].

Among HD patients, the use of bioincompatible membranes can cause additional amino acid losses and dialyzer reuse, especially when treated with bleach, and has been associated with up to 20 g of protein loss per dialysis treatment [159].

### Non-CKD-related factors

**Increased proteolysis** Insulin resistance in MHD patients both with [166] and without [167] type 2 diabetes has been associated with muscle protein breakdown. Furthermore, adiposity is one contributing factor to insulin resistance [168] that may in turn lead to further muscle protein breakdown.

### Decreased regaining protein or energy

#### Chronic kidney disease–related factors

**Decreased appetite or dietary intake** Advanced CKD can lead to poor dietary intake as a result of uremic toxins, inflammation, and underlying medical and psychological illnesses, including depression or dementia [146].

Many factors affect appetite, including a change in regulatory hormones (e.g., leptin [169–171] and visfatin [172]) and inflammatory cytokine levels [101]. Furthermore, imposed dietary restrictions as well as polypharmacy, especially with phosphate binders or other medications that can cause gastrointestinal-related side effects, can also cause low caloric intake [173].

#### Dialysis-related factors

**Decreased appetite or dietary intake** Among PD patients, dwelled intraabdominal dialysate can cause

fullness and decreased appetite independent of the intragastric pressure increases from dialysate [174].

Moreover, hyperglycemia from glucose absorption from peritoneal dialysate either from continuous glucose absorption [175] or when using hypertonic dialysate exchanges in volume overload can suppress appetite through hyperglycemia-induced anorexia [175,176].

Additionally, the poor appetite may result from inadequate dialysis and uremic toxin buildup, especially with inappropriate or unadjusted dialysis prescriptions when residual renal function declines. On the other hand, longer dialysis duration can also predispose to greater risk of inadequate energy and protein intake [177].

### Non-CKD-related factors

**Decreased appetite or dietary intake** Several non-CKD-related factors can also be associated with decreased appetite and dietary intake. Aging itself is also associated with decreased DPI in elderly men [178], and among diabetic CKD, patients with gastroparesis and delayed gastric emptying can exacerbate low appetite. Addition of other medical comorbidities such as congestive heart failure, chronic pulmonary diseases, and malignancies is also associated with PEW [179].

**Decreased food access** Poor socioeconomic status contributes to food insecurity that leads to poor nutrition and can also lead to volume overload from edematous states in ESKD [146].

### Risk factors of frailty

CKD and age remain two of the strongest risk factors for frailty, though neither age nor comorbidities are enough for the diagnosis of frailty. Additional comorbidities related to CKD also play an important role (Table 12.11 and Fig. 12.5).

#### Aging

Age-related frailty may result from genetic or environmental factors.

#### Genetic factors

**Muscle abnormalities (sarcopenia)** We are beginning to understand that some neurohormonal pathways are related to human longevity and SKM. For example, age-related growth hormone deficiency can lead to decreased levels of IGF-1, an anabolic, antiapoptotic hormone that has been shown to maintain muscle mass and improve physical performance [180,181]. The loss of muscle mass and strength (i.e., sarcopenia) can ultimately decrease exercise capacity and potentially lead to frailty [182].

Vitamin D deficiency, common among elderly and patients with decreased skin thickness, is also associated

with type II muscle fiber atrophy and a subsequent decrease in physical performance [183–185].

**Neuronal abnormalities** In addition to muscular issues that can contribute to frailty, neurological issues may also contribute to sarcopenia and frailty in the elderly. These neurological issues include the loss of lower motor neurons, especially in elderly individuals over 60 years old as well as a decrease in the number and diameter of motor axons, a decrease in peroneal nerve conduction velocity, and a reduction in compound muscle action potentials [186,187].

Denervation found in elderly individuals also causes a disproportionate loss of fast muscle motor units (type II fibers) compared to the slow motor units (type I fibers). The loss of type II fibers also causes a net conversion of type II fibers to type I fibers due to the recruitment of denervated type II fibers by the surviving type I fibers [188,189].

Satellite cell proliferation and differentiation are decreased in the elderly due to decreased or delayed expression of myogenic regulatory factors, including myogenic determination factor, myogenic regulatory factor 5, and myogenin [190].

## Environmental factors

**Gene- and chromosome-related factors** Environmental factors that contribute to frailty include abnormal gene and chromosome such as oncogene expression, DNA damage, telomere shortening [191–193], dysfunction of cellular organelles such as mitochondrial dysfunction [194,195], cellular apoptosis and autophagy [196,197], and inflammatory process such as oxidative stress [194,195], and free radical accumulation [193,198]. These lead to accumulated dysfunctional senescent cells, tissues, and organ systems [193,199] that can also lead to frailty over time.

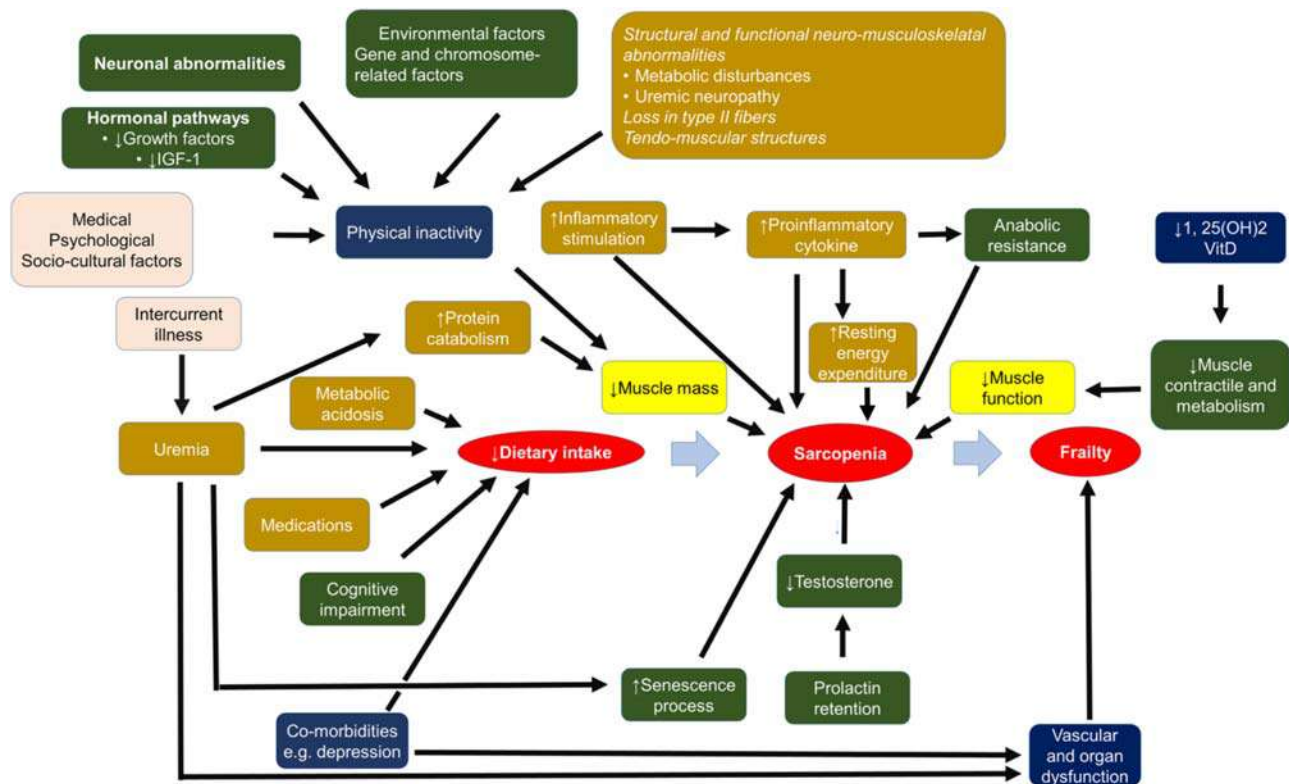

FIGURE 12.5 Pathophysiology of frailty in CKD and end-stage kidney disease patients. Three main factors include aging (green boxes), CKD (brown boxes), non-CKD (pink boxes), and combined factors (blue boxes). 1,25-(OH)<sub>2</sub>D, 1,25-Dihydroxycholecalciferol; 25(OH)<sub>2</sub>D, 25-hydroxycholecalciferol; CKD, chronic kidney disease; IGF-1, insulin-like growth factor 1.

### Chronic kidney disease–related factors

There are also many CKD-related factors that should be considered. Metabolic disturbances from CKD can lead to both structural and functional neuromusculoskeletal abnormalities. In addition, uremia causes impaired sensation, hypoesthesias, reduced deep tendon reflexes, paresis, and paralysis [146]. These can potentially contribute to decreased ambulation and other types of physical activity, especially in a population that is already prone to physical inactivity [200].

Vitamin D deficiency due to CKD can also result in abnormalities in muscle function placing CKD and ESKD patients at greater risk of frailty and sarcopenia compared to non-CKD patients. In addition, high calcium deposition found in late CKD and ESKD patients may interfere with tendomuscular structures and function that can result in rupture or separation of tendons from their bony insertion sites when subjected to increased contractile force [201,202]. These factors ultimately can lead to low physical activity and frailty.

### Non-CKD-related factors

In addition to CKD-related factors that contribute to the development of frailty, there are non-CKD-related

factors such as psychological and sociocultural factors that may also increase the risk of developing frailty. For example, congenital or acquired medical conditions leading to neuromuscular disorders can prevent individuals from being active such as congenital or acquired causes of neuromuscular disorders. Also, mental disorders such as depression can decrease their motivation to exercise or perform physical activity in addition to itself being a risk factor for frailty [203]. Sociocultural issues and the lack of health literacy can also predispose to unhealthy lifestyle habits and a lower level of physical activity.

The dynamic interaction between PEW and frailty overtime through the CKD spectrum ultimately leads to additional age-related syndromes such as cachexia and sarcopenia (Fig. 12.6). Both PEW and frailty are complex clinical syndromes with overlapping pathophysiology that contribute to poor patient outcomes, especially among CKD and ESKD patients. While researchers have yet to determine a standard definition of frailty, the field is constantly evolving, and our understanding of these complex clinical syndromes is continuously improving. With advances in this field, we hope that the development of better screening tools can assist with furthering identifying at-risk patients, improving prognostication to

FIGURE 12.6 Dynamic of protein-energy wasting and frailty in chronic kidney disease and end-stage kidney disease patients. The longer the dialysis vintage, the higher the risk of protein-energy wasting and frailty. The severe frailty spectrum is cachexia. However, with a decrease in net energy expenditure, body mass index may increase and this leads to another phenotype of the frailty of sarcopenic obesity.

better counsel our patients, and mitigating unfavorable outcomes in this high-risk population.

official opinion of any US Department of Veterans Affairs.

## Acknowledgments

The authors appreciate our patients for the knowledge and experience we gain from clinical care and research.

### Funding sources

Supported by research grants from the National Institute of Diabetes, Digestive and Kidney Disease of the National Institutes of Health K24-DK091419, and philanthropic grants from Mr. Louis Chang and Dr. Joseph Lee.

### Potential conflict of interests

KK-Z has received honoraria and/or grants from Abbott, Abbvie, Alexion, Amgen, DaVita, Fresenius, Genzyme, Keryx, Otsuka, Shire, Rockwell, and Vifor, the manufacturers of drugs or devices and/or providers of services for CKD patients.

### Important disclosure

KK-Z and JS serve as physicians in US Department of Veterans Affairs medical centers with or without compensation or are part- or full-time those medical centers. Opinions expressed in this chapter are absolutely those of the authors and do not represent the

## Abbreviations

ADL	activities of daily living
BADL	basic activities of daily living
BF	body fat
BIA	bioelectrical impedance analysis
BMI	body mass index
BUN	blood urea nitrogen
CFS	Clinical Frailty Scale

# Causes and treatment of protein-energy wasting in kidney disease

*Keiichi Sumida and Csaba P. Kovesdy*

Division of Nephrology, Department of Medicine, University of Tennessee Health Science Center, Memphis, TN, United States

Protein-energy wasting (PEW), defined as “loss of body protein mass and fuel reserves,” is one of the most serious complications of chronic kidney disease (CKD) and is frequently encountered not only in nondialyzed patients with advanced CKD but also in those individuals with end-stage renal disease (ESRD) who are receiving maintenance hemodialysis (HD) or chronic peritoneal dialysis (PD) therapy. There are many causes of PEW in CKD, and these include a wide array of disorders or factors that may or may not be related directly to the underlying renal failure: anorexia, decreased nutrient intake, endocrine disorders, inflammatory cytokines, metabolic acidosis, oxidative and carbonyl stress, volume overload, comorbid conditions, nutrient loss during the dialysis procedure, and other dialysis treatment–related factors. Multifaceted and individualized approaches are required for the prevention and treatment of PEW, including optimizing dietary nutrient intake and physical exercise, prescribing optimized dialytic regimens, and appropriate treatment of metabolic disturbances such as hormonal deficiencies, metabolic acidosis, and systemic inflammation. A number of interrelated mechanisms and mediators involved in the pathophysiology of PEW in CKD, as well as its therapeutic maneuvers, are discussed.

## Introduction

PEW represents one of the most serious complications of CKD [1] and poses a formidable therapeutic challenge because (1) it is common and is frequently encountered not only in individuals with ESRD who are receiving maintenance HD or chronic PD therapy but also in nondialyzed patients with CKD, (2) it is caused by a wide

range of disorders or factors that may or may not be related directly to the underlying kidney disease [2], and (3) it can cause severe and prolonged debilitation leading to poor quality of life. In addition, PEW assumes an even greater significance because it often coexists with other comorbid risk factors, such as diabetes, inflammation, and atherosclerosis, and is powerfully associated with all-cause mortality, adding further to the excess morbidity and mortality in the ESRD population [3,4].

In recent years, it has become increasingly apparent that the wasting syndromes attributed to PEW are not merely the result of undernutrition with reduced intake of protein and energy but may also involve other factors or conditions that reduce muscle mass or increase fat loss and/or energy expenditure. Based on new findings concerning syndromes of muscle wasting, malnutrition, and inflammation in individuals with acute kidney injury (AKI), or CKD, the International Society of Renal Nutrition and Metabolism (ISRNM) expert panel proposed in a 2008 report new terminologies and definitions related to wasting, cachexia, malnutrition, and inflammation [5]. The term “protein-energy wasting,” previously referred to as “protein-energy malnutrition,” is now defined as the state of decreased body stores of protein and energy fuels (i.e., body protein and fat masses). “Kidney disease wasting” is used by some nephrologists to refer to the occurrence of PEW in CKD or AKI, regardless of the cause. Since many causes of PEW in CKD or AKI are similar to the causes of PEW in other chronic or acute diseases, many nephrologists prefer to use the term PEW for protein and/or energy wasting that occurs in kidney disease. This emphasizes the similarity for most causes of PEW in these various disease states. Cachexia refers to a severe form of PEW

**TABLE 13.1** Protein-energy wasting (PEW) diagnostic criteria suggested by the PEW consensus conferences [5].

<b>Primary criteria</b>
1. Biochemical markers

3. Other laboratory biomarkers
4. Nutritional scoring systems
5. Other novel markers

that occurs infrequently in kidney disease. Diagnostic criteria for PEW are shown in Table 13.1. While markers of chronic inflammation or other novel biomarkers can be useful clues for the existence of PEW, such measures do not define the condition.

This chapter focuses on the causes and treatment of PEW in CKD and examines the evidence for the role of molecular, biochemical, nutritional, as well as environmental factors involved in the pathogenesis of PEW, which in turn is key to formulating strategies for the prevention and treatment of this common and debilitating disorder.

### Causes of protein-energy wasting in chronic kidney disease

PEW may be viewed as a complex heterogeneous disorder that results from an interplay of multiple factors that directly or indirectly alter protein metabolism and energy balance. There are many causes of PEW in CKD, and these encompass a wide variety of conditions or disorders that ultimately lead to decreased protein and energy intake, increased protein loss or energy expenditure, or a combination of both factors as shown in Table 13.2.

### Pathophysiology of protein-energy wasting in chronic kidney disease

The pathophysiologic basis of PEW in CKD is multifactorial as depicted in Fig. 13.1. Before discussing the mechanisms of wasting in CKD, a few general considerations merit special attention. First, the factors involved in the regulation of nutrient intake, protein metabolism, and energy balance are diverse, and their relative contribution to wasting in PEW may vary in importance depending upon the nature

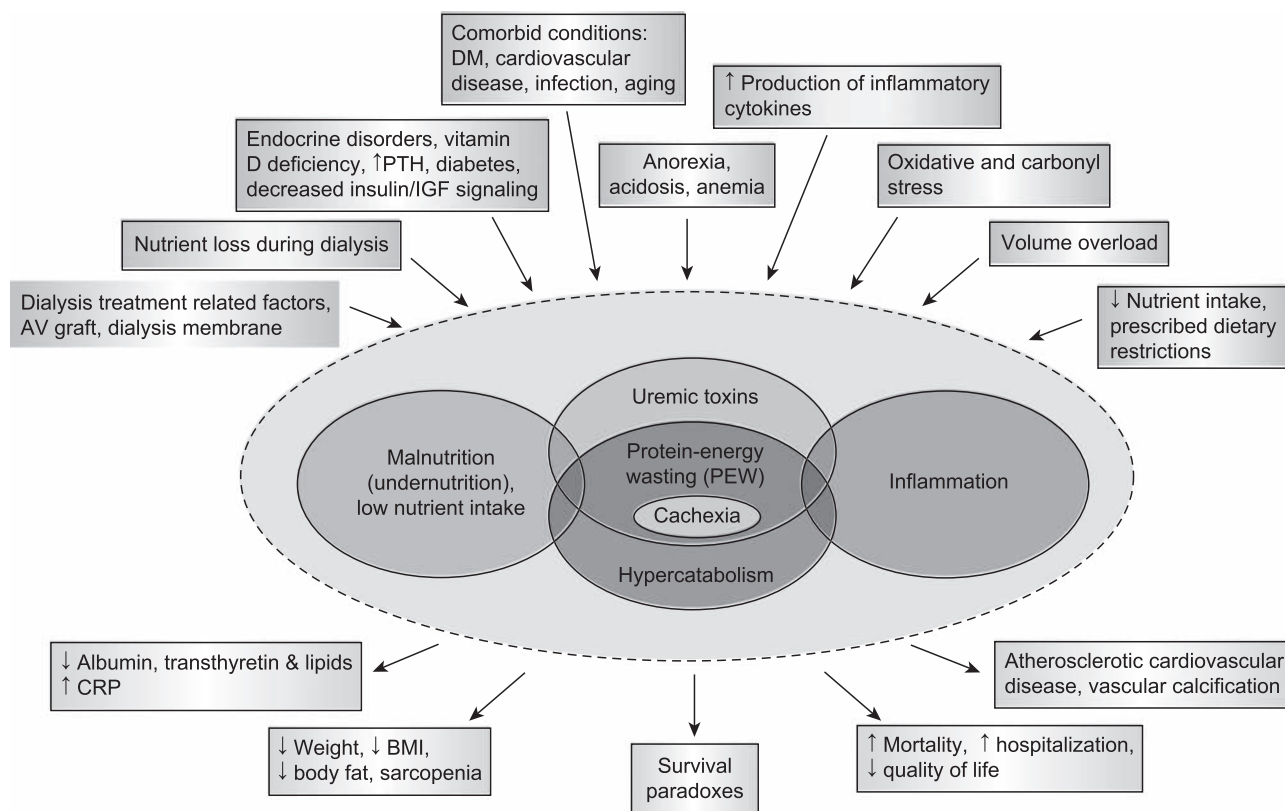

**TABLE 13.2** Causes of protein-energy wasting in chronic kidney disease/end-stage renal disease.

1. Anorexia
2. Decreased nutrient intake
3. Endocrine disorders:
insulin resistance
decreased insulin-like growth factor-I
hyperglucagonemia
testosterone deficiency
vitamin D deficiency
hyperparathyroidism
4. Inflammation
5. Oxidative and carbonyl stress
6. Metabolic acidosis
7. Volume overload
8. Comorbid conditions, including diabetes and cardiac failure
9. Nutrient loss during dialysis treatment
10. Increased energy utilization
11. Abnormal protein kinetics

of the inciting stimulus or event that occurs during the evolution of the disease. Second, given the chronicity and varying comorbid conditions associated with CKD, mechanisms that initiated PEW may not be operative at the later stages of the disease, and as kidney disease progresses to end stage, other potential mechanisms may come into play. Third, there are inherent redundancies in molecular, cellular, and biochemical events that regulate protein and energy metabolism in a given individual, as there are in the biologic activities of various peptides, cytokines, and hormones. Thus there are independent, overlapping, and complementary or antagonistic mechanisms of action, which make it difficult to disentangle their effects on protein metabolism and/or energy balance. Nonetheless, the accumulated scientific data may provide the framework for formulating targeted interventions to prevent or reverse PEW in patients with CKD.

### Anorexia

Anorexia is a cardinal manifestation of CKD. Several factors have been proposed to account for the anorexia associated with kidney disease. Evidence that uremic toxins can suppress appetite and food intake is derived from the studies of Anderstam and coworkers [6] in experimental animals showing that intraperitoneal injection of uremic plasma ultrafiltrate into normal rats inhibits ingestion of nutrients. A dose-dependent effect was noticed only with the subfractions with molecular weight ranges of 1–5 and 5–10 kDa, respectively, whereas fractions with molecular weights below 1 kDa had no effect. In a subsequent study the same group of investigators showed that intraperitoneal injection of a

**FIGURE 13.1** Schematic representation of the causes and manifestations of the protein-energy wasting syndrome in kidney disease. Source: Reprinted from Fouque D, Kalantar-Zadeh K, Kopple J, et al. A proposed nomenclature and diagnostic criteria for protein-energy wasting in acute and chronic kidney disease. *Kidney Int* 2008;73:391–8.

urine fraction or uremic plasma ultrafiltrate fraction inhibited carbohydrate intake by 76.3% and 45.9%, respectively [7]. An intracerebroventricular injection of 5 or 10  $\mu$ L of urine middle molecule fraction (i.e., compounds with a molecular weight range of 300–2000 Da) significantly inhibited carbohydrate intake. These data suggest that middle molecule compounds that accumulate in the plasma of uremic patients suppress food intake.

## Decreased nutrient intake

Inadequate nutrient intake is considered the most important single cause of PEW in CKD and has been well documented in both adults and children with varying degrees of kidney failure [5,8]. The decline in dietary intake occurs early in CKD and accelerates as renal failure worsens. In children with CKD, low protein or energy intake due to anorexia is the primary reason for growth failure in this group [9]. In a prospective study, Ikizler [10] showed that spontaneous dietary protein intake (calculated from 24-hour urine urea excretion) of patients with CKD significantly decreases as renal function declines. This decrease is

most noticeable at creatinine clearance levels below 25 mL/min. In a large cohort of adult patients with moderate-to-advanced CKD, Kopple et al. [11] showed that dietary protein intake and nutritional status correlated directly with the GFR. Especially, patients with a GFR of 21 mL/min/1.73 m<sup>2</sup> or lower showed greater decline in nutritional status. Thus intake of dietary protein and calorie declines with decrease in GFR. The other factors that could contribute to decreased nutrient intake include depression, dementia, and even economic barriers [12].

## Impaired gastric motility

Several studies have documented an impairment of gastric motility in ESRD patients [13,14]. In one study, more than 50% of nondiabetic ESRD patients receiving maintenance dialysis had abnormal gastric myoelectrical activity [15]. Furthermore, administration of prokinetic agents to hypoalbuminemic nondiabetic maintenance HD patients with occult gastroparesis was shown to improve gastric emptying, an effect that was accompanied by an increase in serum albumin [16]. The mechanism for the gastroparesis in ESRD patients is

unclear, but it has been postulated that derangements in neuroendocrine signaling and imbalance in gut-derived hormones may play a pathogenic role.

## **Endocrine and hormonal disorders**

CKD is characterized by a plethora of endocrine disorders resulting from either an increased or decreased level of hormones or impaired action at the target tissue level. We will review the association between endocrine/hormonal dysfunction and its role in the pathogenesis of PEW.

### **Gut-derived hormones**

The gut produces peptides that have autocrine and paracrine as well as endocrine functions. These gut-derived peptides maintain mucosal integrity, facilitate secretion of digestive enzymes, modulate gut motility, and signal to the brain regarding the presence and absorptive status of nutrients; thus they could play an important role in the genesis of PEW.

Ghrelin is a unique hormone, principally secreted from the stomach. It acts to stimulate appetite and food intake via stimulation of the type 1a growth hormone (GH) secretagogue receptor [17]. Since ghrelin is a potent appetite enhancer, it was initially thought that reduced levels of circulating ghrelin might be a potential mechanism for the reduced appetite seen in CKD. Surprisingly, plasma ghrelin was found to be elevated in patients with ESRD [18], and circulating ghrelin levels were found to be significantly higher in uremic patients with poor appetite when compared with uremic patients with good appetite [19]. Subsequent studies have revealed that ghrelin circulates in both an acylated [acyl ghrelin (AG)] and des-acylated forms [des-acyl ghrelin (DG)] [20], and that AG has potent orexigenic activity and induces an increase in food intake, while DG exerts opposing actions to AG [21]. In patients with ESRD, the altered ghrelin metabolism associated with uremia results in an increased DG/AG ratio and resultant anorexigenic transcripts in the hypothalamus, which leads to decreased food intake and gastric emptying and promotes PEW [21]. Recent studies have also shown that exogenous administration of ghrelin increases AG levels and improves appetite and/or increases food intake in animals and humans with CKD [22,23]. Thus exogenous administration of ghrelin appears to be a promising strategy to improve food intake in malnourished ESRD patients.

Peptide YY (PYY) is another gut-derived hormone that plays an important role in the short-term regulation of appetite [24]. This peptide is released by intestinal

L cells in response to meals, suppresses appetite, and acts as a “break” to oral intake by complex mechanisms, which include vagal stimulation through interaction with the receptor Y2 (Y2R) of the hypothalamic arcuate nucleus. Increased plasma levels of PYY have been reported in patients with ESRD treated with dialysis, which could contribute to the anorexia and PEW of CKD [25].

Cholecystokinin (CCK) is an intestinal hormone known to cause early satiety and suppress appetite [26]. It is released in response to eating and induces a state of satiety via peripheral and central receptors. Because circulating levels of CCK are increased in ESRD patients, it has been suggested that CCK may contribute to the premature satiety and anorexia in CKD. Experimentally, administration of CCK has been shown to induce premature satiety with shortening of the eating period and reduced nutrient intake [27].

### **Insulin and insulin-like growth factors**

The most common and important endocrine disorder in CKD is the development of insulin resistance [28]. Insulin is a potent anabolic hormone; even a small increase in plasma insulin stimulates protein synthesis and exerts a powerful inhibitory effect on protein catabolism [29]. Resistance to the actions of insulin has been shown to be strongly associated with increased muscle breakdown in nondiabetic chronic HD patients [30].

Insulin-like growth factor-I (IGF-I), which has a 48% amino acid sequence identity with proinsulin, enhances insulin sensitivity and independently stimulates protein synthesis and suppresses protein degradation in both experimental animals and human subjects. Kopple and associates showed that mRNA levels of IGF-IEa, IGF-II, and the IGF-I receptor are decreased in the skeletal muscle of ESRD patients [31]. There is an attenuation in the IGF-I-induced stimulation of protein synthesis and inhibition of protein degradation in skeletal muscle in CKD [32]. Among the known mechanisms for IGF-I resistance in CKD are defects in the phosphorylation and activity of the intrinsic tyrosine kinase of the IGF-I receptor and plasma inhibitors of IGF-I and elevated basal cytosolic  $[Ca^{2+}]$  [30]. Bailey et al. [33] have shown that CKD causes defects in IGF-I signaling in skeletal muscle, an effect that is associated with a decrease in phosphorylation of Akt (protein kinase B) and an increase in proteolysis and muscle wasting. Another mechanism closely linked to impaired IGF-I signaling in CKD is dysfunction of skeletal muscle precursors or satellite cells, which are responsible for maintaining muscle growth and repair [34].

Interestingly, administration of thiazolidinedione (TZD) in a rodent model of insulin resistance improved insulin resistance and decreased protein degradation in muscle [35]. Furthermore, in a recent clinical study of a large cohort of incident HD patients with diabetes, non-insulin requiring type-2 diabetic subjects receiving TZDs had significantly higher body mass indices, and serum albumin levels, than those not receiving TZDs [36].

## Resistance to growth hormone

GH is the major promoter of growth in children and exerts anabolic actions even in adults: protein synthesis, reduced protein degradation, increased fat mobilization, and increased gluconeogenesis, with IGF-I being the major mediator of these actions [37]. It also regulates muscle and fat metabolism, which impacts body composition and insulin sensitivity. Decreased or impaired action of GH is another endocrine disturbance associated with CKD that may retard muscle growth and promote muscle protein catabolism [38]. Insensitivity to GH is the consequence of multiple defects in the GH/IGF-I signaling. GH activation of the Janus kinase 2-signal transducer (JAK2) and activator of transcription (STAT) signal transduction pathway is depressed in advanced CKD, and this leads to reduced IGF-I expression and resistance to IGF-I [39]. Interestingly, similar biochemical abnormalities can also be observed with decreased dietary protein, and during experimental metabolic acidosis [40], suggesting that an interrelationship between these hormonal, metabolic, and nutritional factors is involved in the development of PEW in patients with CKD.

## Testosterone deficiency

Hypogonadism is a frequent endocrine disorder in men undergoing dialysis, and more than 60% of men with advanced CKD have low plasma concentrations of testosterone [41]. Testosterone regulates many physiological processes, including sexual function, cognitive functions, erythropoiesis, plasma lipids, and bone mineral metabolism, and testosterone deficiency is associated with sexual disorders, worse quality of life, poor graft survival, and increased mortality risk [42]. In view of its physiological effects as an anabolic hormone, testosterone plays an important role in inducing skeletal muscle hypertrophy [42]. It facilitates muscle anabolism by, among other mechanisms, promoting nitrogen retention, stimulating fractional muscle protein synthesis, inhibiting muscle protein degradation, and augmenting the efficiency of amino acid reuse by skeletal muscle [43]. In patients with CKD, testosterone synthesis is severely diminished, mainly because of reduced prolactin clearance and uremic inhibition of

luteinizing hormone signaling, which has been associated with reduced muscle strength and fat-free mass contributing to the development of PEW in CKD [44].

## Altered adipokine physiology

Adipose tissue has traditionally been viewed as a passive reservoir for storage of energy. However, in recent years, it has emerged as a highly active endocrine organ that secretes a variety of bioactive peptides, known as adipokines, which mediate numerous biological and pathological processes, including energy metabolism, neuroendocrine function, sex steroid metabolism, and immune function. The underlying mechanisms whereby endocrine hormones and adipokines cause anorexia and decreased nutrient intake in CKD are complex and may involve the participation of neuroendocrine pathways that control food intake and energy homeostasis (Fig. 13.2).

Leptin, the protein product of the *ob*-gene, is secreted by adipocytes and acts as a lipostat mechanism to regulate food intake and energy expenditure via modulation of satiety signals in the hypothalamus [46]. An increase in the level of leptin decreases neuropeptide Y, reduces food intake, increases energy expenditure, induces weight loss, lowers plasma insulin, alters glucose homeostasis, and induces muscle protein breakdown. Serum leptin concentrations are elevated in CKD patients who do not have ESRD [47], as well as in patients undergoing renal replacement therapy [48] and have been shown to be inversely correlated with dietary protein intake [49]. Longitudinal studies have also shown that increased serum leptin levels are associated with weight loss in dialysis patients [50]. Moreover, experimental studies in leptin receptor-deficient mice made cachectic by nephrectomy have shown that uremia-associated cachexia is caused by leptin signaling through the hypothalamic melanocortin receptor 4 [51]. These results suggest that increased circulating leptin may be an important mediator of uremia-associated cachexia via signaling through the central melanocortin system. However, other anorexigenic and catabolic pathways besides leptin cascade may be important.

Adiponectin is another adipocyte-derived hormone that has been shown to modulate food intake and energy homeostasis [52]. In addition, adiponectin has insulin-sensitizing, antiatherogenic, and antiinflammatory properties. Data regarding the role of adiponectin in PEW in CKD are limited. Despite the high prevalence of insulin resistance in CKD, circulating levels of adiponectin are increased among patients with CKD [53–55]. Surprisingly, in ESRD patients undergoing maintenance dialysis serum, adiponectin levels were positively

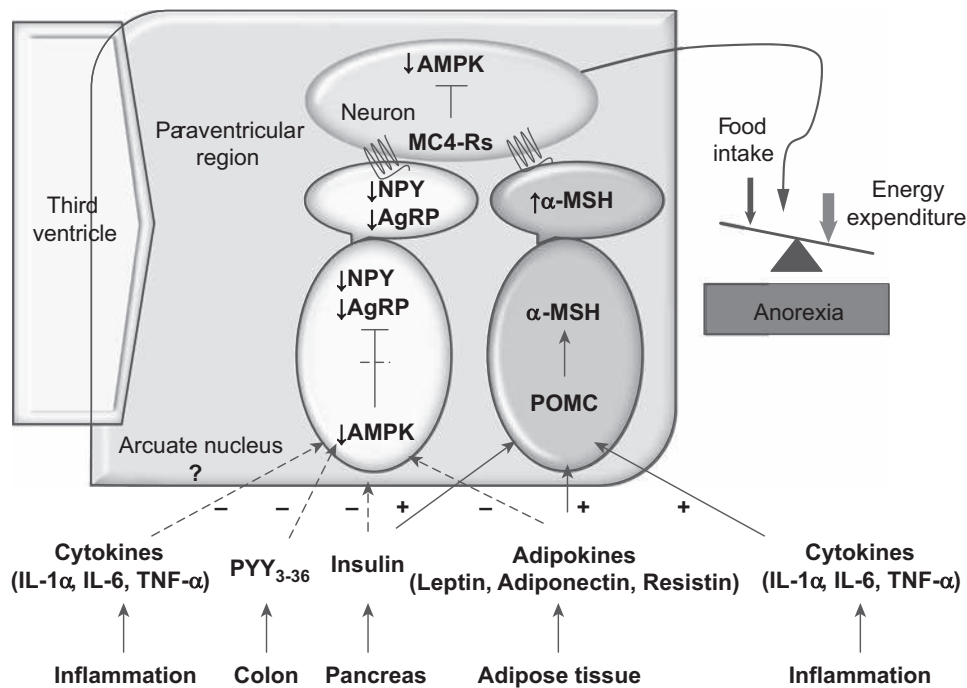

FIGURE 13.2 Orexigenic and anorexigenic mechanisms controlling energy homeostasis in CKD. Circulating hormones produced by the colon (PYY), pancreas (insulin), adipose tissue, and cytokines all cause anorexia. Responses to these factors result in the modulation of the hypothalamic melanocortin signaling pathways with an increase in MC4-Rs that suppresses AMPK activity, leading to decreased food intake, increased energy expenditure, and weight loss. AMPK, AMP-activated protein kinase; CKD, chronic kidney disease; PYY, peptide YY [45]. Source: Reprinted with permission from Mak RH, Cheung W, Cone RD, Marks DL. Orexigenic and anorexigenic mechanisms in the control of nutrition in chronic kidney disease. *Pediatr Nephrol* 2005;20:427–31.

correlated with worse malnutrition–inflammatory scores [56]. It is speculated that the apparent unfavorable effect of high adiponectin might not necessarily be related to a direct effect of adiponectin, but rather it could be a consequence of a concurrent process of wasting with a secondary increase in adiponectin levels [57].

inflammation, and atherosclerosis among PD patients [62]. These data suggest that there may be a link between the malnutrition–inflammatory state and hypervolemia in patients with CKD.

### Contribution of comorbidities

#### Effect of volume overload

Chronic volume overload and concomitant heart failure are frequent complications of CKD. There is increasing evidence that fluid volume overload may contribute to malnutrition in CKD patients that may contribute to PEW. For instance, volume overload is associated with inadequate dietary protein and energy intake [58] and nutritional status in maintenance PD patients [59]. In a large cohort of ESRD patients undergoing renal replacement therapy, plasma levels of the N-terminal fragment of B-type natriuretic peptide (NT-proBNP) and the extracellular fluid volume/total body water (ECFv/TBW) ratio were correlated with several markers of inflammation and poor nutrition [60,61]. Furthermore, chronic fluid overload, as measured by multifrequency bioimpedance analysis, is significantly correlated with markers of malnutrition,

A number of comorbid diseases or conditions that are prevalent in ESRD patients may also contribute to PEW in such patients [4,63]. These include diabetes, hypertension, atherosclerosis, chronic heart failure, intercurrent catabolic illnesses such as infections, and advanced age. In addition to the hyperglycemia and insulin-resistant state in diabetes, other comorbid disorders related to diabetes, including gastrointestinal dysfunction, hypertension, ischemic vascular disease, and neuropathy, may reduce food intake and add to protein wasting in CKD patients. Patients with CKD frequently sustain acute intercurrent illnesses that may also reduce food intake and induce a negative nitrogen balance. In addition, many patients with ESRD have evidence of atherosclerotic cardiovascular disease (CVD) that is associated with malnutrition or PEW and increased levels of proinflammatory cytokines [4]. Because of the strong associations between malnutrition, inflammation, and atherosclerosis in CKD, it has been proposed

that these features constitute a specific syndrome termed “malnutrition–inflammation–atherosclerosis”, which carries a high mortality rate.

### Altered protein kinetics in chronic kidney disease

An increase in net proteolysis due to imbalance between protein synthesis and degradation has been reported in uremic animals [64]. The results from the human studies, however, are more controversial than those from animal studies. Muscle and whole-body protein turnover studies in stable advanced CKD/ESRD patients have consistently shown that there is a balanced reduction in protein synthesis and degradation, such that there is no net protein loss [65–67]. On the other hand, investigators unanimously agree that HD induces protein catabolism. Lim et al. [68] reported normal basal leucine flux, a transient decrease in protein synthesis and a negative protein balance during HD. Ikizler [69] found that protein catabolism is increased during HD, with no significant change in protein synthesis. Using multiple tracers, Raj et al. [67] observed a significant increase in both protein synthesis and breakdown during HD. However, the intradialytic increase in catabolism exceeded that of synthesis, resulting in net muscle protein loss.

Albumin is a negative acute-phase protein, and fibrinogen is a positive acute-phase protein. In healthy humans, albumin and fibrinogen account for ~50% and ~10% of the total liver protein synthesis, respectively. The changes in albumin, fibrinogen, and muscle protein synthesis rates vary according to the pathophysiological state. For instance, albumin and fibrinogen synthesis rates increase in nephrotic syndrome [70]. However, in inflammatory states, the synthesis rates for albumin, fibrinogen, and muscle protein may show a concomitant increase or they may be discordant depending on the cause, intensity, and duration of inflammation [71,72]. Giordano et al. [73] reported that synthesis rates of albumin and fibrinogen are increased in ESRD patients with normal nutritional status. Kaysen et al. found that albumin synthesis is lower in hypoalbuminemic ESRD patients, and that albumin synthesis and catabolism in ESRD are modulated by inflammation [74,75]. Caglar et al. [76] observed that the intradialytic increase in albumin synthesis rate (64%) was higher than that of fibrinogen (34%), but Raj et al. [77] noted that the fractional synthesis rate of fibrinogen (53.5%) tended to be larger than that of albumin (38.6%) during HD. Thus protein catabolism appears not to be increased, even in advanced CKD, in the absence of other superimposed illnesses.

PD treatment provides 300–600 kcal/day primarily from absorption of glucose from the use of dextrose-based dialysis solutions resulting in hyperinsulinemia in these patients. Goodship et al. [78] performed leucine turnover studies in CKD patients before and after 3 months of continuous ambulatory PD (CAPD) treatment. They observed that protein turnover was decreased at baseline, but the balance between synthesis and breakdown was higher and remained unchanged after 3 months on CAPD. Long-term use of amino acid–based PD fluid has been shown to induce a positive protein balance [79]. About 80% of leucine contained in the dialysate solution is absorbed through peritoneum and about 43% of the leucine absorbed is used for protein synthesis [80].

### Nutrient loss during dialysis

Chronic blood loss and losses of several nutrients, including glucose, amino acids, peptides, and proteins, as well as water-soluble vitamins during the dialysis may contribute to the pathogenesis of PEW in ESRD patients. Raj et al. [81] studied the alanine and glutamine kinetics in ESRD patients using a three compartmental model (artery, vein, and muscle) and showed that the intracellular amino acid concentration is maintained during HD by muscle protein catabolism. However, they noted that amino acid infusion during dialysis increased muscle protein turnover, with a balanced increase in both protein synthesis and breakdown [82]. On the other hand, Pupim et al. [83] demonstrated that intradialytic parental nutrition increases whole-body protein synthesis and decreases proteolysis. Forearm muscle protein kinetics, however, showed that while protein synthesis is increased, protein breakdown is unchanged. Thus it appears that amino acid repletion increases protein synthesis without a significant impact on muscle protein catabolism.

### Inflammation: agent provocateur of protein-energy wasting

A large body of evidence indicates that inflammation plays a central role in the pathogenesis of PEW in CKD beyond its role in protein catabolism. For example, cytokines, such as tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1, and IL-6, can cause anorexia by acting on the central nervous system via modulation of the melanocortin signaling system to alter the release and function of several key neurotransmitters that regulate appetite and metabolic rate (Fig. 13.3). IL-1 has been shown to inhibit gastric emptying, an effect mediated in part by CCK release.

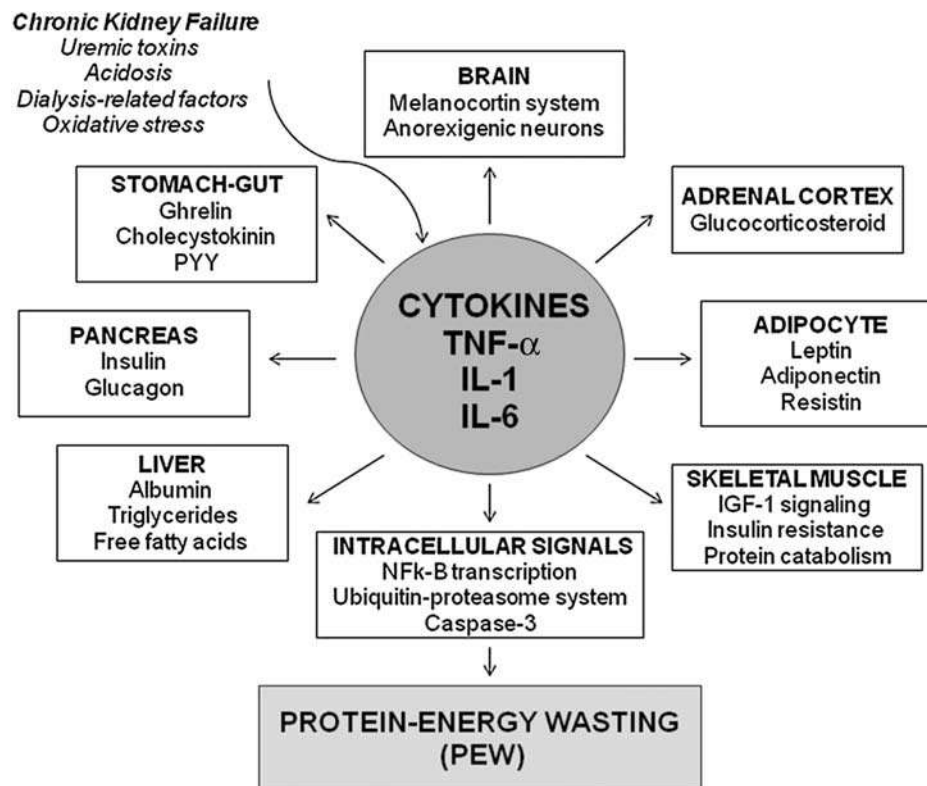

FIGURE 13.3 Central role of cytokines in the pathophysiology of protein-energy wasting in CKD. CKD, Chronic kidney disease.

It is becoming increasingly clear that intradialytic loss of amino acids, and the resultant deficiency of amino acids, is only a part of the paradigm, the other being cytokine activation facilitating augmented protein catabolism [84]. Besides peripheral blood mononuclear cells, human skeletal muscle cells appear to have the inherent ability to express a variety of cytokines [85,86]. Muscle-derived IL-6 functions as an exocrine hormone, exerting its effects on the liver and adipose tissue. Raj et al. [85] demonstrated that cytokines are released from the muscle into the vein during HD. Furthermore, they showed that IL-6 leads to activation of genes promoting protein catabolism [87], efflux of amino acids from the muscle [82] and increased synthesis of hepatic acute-phase proteins during HD [88] (Fig. 13.4). The same group of investigators observed that caspase-3 activity in the skeletal muscle, accumulation of 14-kDa actin fragment (a measure of muscle protein breakdown), and apoptosis are increased during HD [89]. Muscle protein catabolism was positively associated with caspase-3 activity and skeletal muscle IL-6 content. These findings suggest that muscle atrophy in ESRD may also be caused by IL-6-induced activation of caspase-3 resulting in apoptosis as well as muscle proteolysis during HD (Fig. 13.5).

FIGURE 13.4 Pathophysiology of muscle wasting in CKD. IGF-I increases muscle mass while myostatin inhibits its development. Muscle wasting could be due to imbalance of this regulation. PI3K activity is key to activation of muscle proteolysis through regulation of caspase-3 and expression of atrogin-1/MAFbx. CKD, Chronic kidney disease; IGF, insulin-like growth factor; PI3K, phosphatidylinositol 3 kinase [90]. Source: Reprinted from Cheung WW, Rosengren S, Boyle DL, Mak RH. Modulation of melanocortin signaling ameliorates uremic cachexia. *Kidney Int* 2008;74:180–86.

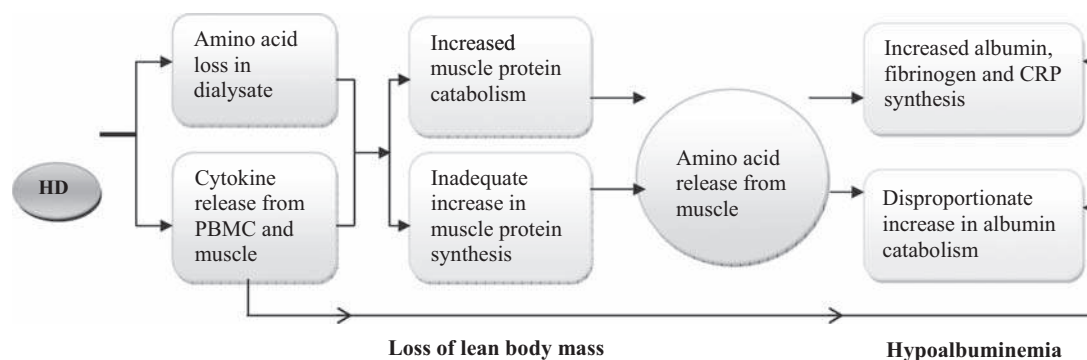

FIGURE 13.5 Integrating cytokine, amino acid kinetics, and protein turnover in ESRD. Activation of cytokines during HD increases synthesis of acute-phase protein, which is probably facilitated by constant delivery of amino acids derived from the muscle catabolism and intradialytic increase in IL-6 [77]. ESRD, End-stage renal disease; HD, hemodialysis; IL, interleukin.

### Role of metabolic acidemia

The National Kidney Foundation Kidney Disease and Dialysis Outcome Quality Initiative guidelines maintain a serum bicarbonate level in ESRD patients of at least 22 mEq/L. Accordingly, in cohort studies, a serum bicarbonate level of >22 mEq/L was associated with lower death risk among ESRD patients [91] and higher bicarbonate concentration was also associated with lower mortality among patients with nondialysis-dependent CKD [92]. Catabolic effects of metabolic acidemia may result from an increased activity of the adenosine triphosphate-dependent ubiquitin-proteasome and branched-chain amino acid oxidation [93]. In addition to its effects on PEW and associations with poorer survival, acidemia may also have deleterious effects on kidney function and may be a risk factor for progression of CKD [94,95]. There may be advantages to increase the arterial pH beyond simply reaching the lower limit of the reference range. In a randomized, crossover metabolic balance study of eight ESRD patients treated with PD, increasing the arterial pH from 7.38 to 7.44 resulted in significantly higher net positive nitrogen balances in all but one patient [96]. Although a few single-center studies have showed that bicarbonate supplementation in patients with CKD improved nutritional status, a recent metaanalysis found no significant benefit of oral alkali supplementation on nutritional assessments in patients with CKD [97]. The potential benefits of alkali therapy on nutritional status have to be balanced with possible adverse effects related to the inadvertent development of alkalemia [98].

### Oxidative stress: other key pathways

CKD is characterized by activation of the renin-angiotensin system. Interestingly, angiotensin II infusion

has been shown to induce skeletal muscle atrophy, which was associated with oxidative stress, increased expression of the E3 ligases atrogin-1/MuRF-1, and augmented ubiquitin proteasome-mediated proteolysis [99,100]. Several lines of evidence link reactive oxygen species (ROS) to muscle atrophy via redox control of proteolysis [101]. Arteriovenous balance studies have shown net release of malonaldehyde and carbonyl protein from skeletal muscle during HD indicating increased generation of ROS. Thus increased oxidative stress could contribute to muscle wasting in CKD.

Nuclear factor- $\kappa$ B (NF- $\kappa$ B) is at the interface between oxidative stress and inflammation and is activated during HD [86]. NF- $\kappa$ B inhibits myogenesis by promoting myoblast growth and inducing loss of MyoD, which stimulates skeletal muscle differentiation and repair [102] (Fig. 13.4). In HD patients the expression of NF- $\kappa$ B has been shown to be negatively correlated with creatinine index, serum albumin, and percentage body fat [103]. In addition, restoring the activity of nuclear factor-erythroid 2-related factor 2 (Nrf2), which is a master regulator of antioxidant genes and is suppressed by NF- $\kappa$ B, has been suggested as a potential therapeutic strategy to reduce oxidative stress and inflammation in CKD [104]. Another molecule, myostatin, a member of the transforming growth factor- $\beta$  superfamily of signal transduction proteins, is an important regulator of skeletal muscle mass and repair [105,106]. Systemic overexpression of myostatin in adult mice was found to induce profound muscle and fat loss analogous to that seen in human cachexia syndromes [107]. Verzola et al. [108] observed that myostatin gene expression is increased in the skeletal muscle of patients with CKD. Thus it appears that activation of multiple pathways distinct and yet interrelated signals mediate muscle atrophy in patients with CKD.

## Treatment of protein-energy wasting in chronic kidney disease

Since the etiology of PEW in patients with CKD is complex and multifactorial, a multidisciplinary, multifaceted, and individualized approach is required to prevent or reverse the PEW in CKD. These include optimizing dietary nutrient intake, appropriate treatment of metabolic disturbances such as metabolic acidosis, systemic inflammation, and hormonal deficiencies, and prescribing optimized dialytic regimens [109]. If these standard preventive measures are unable to effectively diminish the loss of protein and energy stores, additional therapeutic strategies need to be considered.

### Nutritional supplementation

Nutritional supplementation is generally recommended as the first step of nutritional support when dietary counseling and standard preventive measures are not sufficient to achieve the planned nutritional requirements [110]. The indications for the treatment of PEW in patients with CKD recommended by the ISRNm are summarized in Table 13.3 [109]. Oral supplementation should be given two to three times a day, preferably 1 hour after main meals or during dialysis for maintenance HD patients. It can provide an additional 7–10 kcal/kg per day of energy and 0.3–0.4 g/kg per day of protein over a minimum spontaneous intake (i.e., 20 kcal/kg per day of energy and 0.4–0.8 g/kg per day of protein) to meet the recommended dietary energy and protein intake targets [103]. The studies investigating the effects of oral nutritional supplementation (e.g., oral amino acid tables) on the overall nutritional status of HD patients with PEW have yielded encouraging results, showing the improvement of various nutritional parameters such as albumin concentration and lean body mass [111,112]. Moreover, oral nutritional supplementation might have beneficial effects on patient's quality of life, physical functioning, hospitalization rates, and overall survival [113–116].

Although feeding through the gastrointestinal route is preferred for nutritional supplementation, feeding through the parenteral route [i.e., total parenteral nutrition (TPN)] can be considered a safe and convenient approach for patients who cannot tolerate oral or enteral administration of nutrients [109]. In patients on maintenance HD, parenteral nutrition can be conveniently administered during HD treatment via the dialysis tubing [a.k.a. intradialytic parenteral nutrition (IDPN)], which is a significant advantage by eliminating the need for an additional venous catheter placement. In a prospective, randomized, controlled, French Intradialytic Nutrition Evaluation (Fine) study, similar beneficial effects on nutritional status have also been observed for IDPN plus oral supplements (vs oral supplements alone) in HD patients [117]. It is important to note that IDPN should be used as a supplement and not a sole source of nutrients (i.e., it cannot be used as TPN), as in itself it is insufficient to satisfy all the nutrient needs of an individual. According to the results from Fine study, only 6.4 kcal and 0.25-g protein/kg per day were additionally delivered through IDPN plus oral supplements in HD patients [117].

### Exercise

Decreased physical activity plays a major role in the pathophysiology of PEW. Physical activity has been reported to be severely reduced in maintenance HD patients [118,119]. It has been increasingly recognized that regular physical activity improves cardiac function, enhances muscular strength, and increases exercise capacity in patients with CKD [120]. A recent metaanalysis has shown that progressive resistance training not only increases muscular strength accompanied by skeletal muscle hypertrophy but also improves health-related quality of life in CKD patients [121]. Resistance training has been proven safe, feasible, and well tolerated in various clinical settings, including outpatient clinic, home-based regimes, and programs concomitant to dialysis [40]. In addition, a recent study provided compelling evidence that

TABLE 13.3 Indications for nutritional interventions in chronic kidney disease (CKD) patients.

- Poor appetite and/or poor oral intake
- DPI <1.2 (CKD stage 5D) or <0.7 (CKD stages 3 and 4)
- DEI <30 kcal/kg/day
- SAlb <3.8 g/dL or SPreAlb <28 mg/dL
- Unintentional weight loss >5% of IBW or EDW over 3 months
- Worsening nutritional markers over time
- SGA in PEW range

DEI, Dietary energy intake; DPI, dietary protein intake; EDW, estimated dry weight; IBW, ideal body weight; PEW, protein-energy wasting; SAlb, serum albumin; SGA, subjective global assessment; SPreAlb, serum prealbumin.

Adapted from Ikizler TA, Cano NJ, Franch H, et al. Prevention and treatment of protein energy wasting in chronic kidney disease patients: a consensus statement by the International Society of Renal Nutrition and Metabolism. *Kidney Int* 2013;84:1096–107.

regular moderate-intensity aerobic exercise such as walking is safe with regard to immune and inflammatory responses and has the potential to be an effective antiinflammatory therapy in CKD patients [122]. Although studies in ESRD patients have not demonstrated consistent long-term beneficial effects of exercise on clinically relevant outcomes such as improvements in muscle strength and physical functioning, the combination of exercise with nutritional supplementation, along with adequate intensity and/or duration of exercise, may serve as a potential countermeasure for PEW in ESRD [123].

## Pharmacological interventions

Several pharmacological agents have emerged as additional approaches for the treatment of PEW in CKD. These include anabolic agents (e.g., testosterone, GH), appetite stimulants, and antiinflammatory agents.

### Anabolic steroids

Anabolic steroids stimulate net muscle protein synthesis by inducing mRNA expression of skeletal muscle androgen receptor and increasing the intracellular pool of amino acids derived from protein degradation [124]. Administration of supraphysiologic doses of testosterone, especially when combined with strength training, has been shown to increase lean body mass and muscle size and strength in patients with various disease conditions [125–127]. Several randomized controlled trials in both male and female HD patients showed that treatment with nandrolone decanoate significantly increased both anthropometric and biochemical parameters, including body weight, body mass index, skinfold, midarm muscle circumference, and serum levels of total protein, prealbumin, and transferrin [128–130]. In addition, treatment with the androgenic steroid oxymetholone has been shown to be associated with an increase in fat-free mass, handgrip strength, and muscle mRNA levels for several growth factors, together with a decrease in fat mass [131]. It is important to note that the use of anabolic steroids should be limited to 6 months due to their potential side effects [109].

### Recombinant human growth hormone

Administration of recombinant human GH (hGH) has been shown to increase linear growth in children with CKD and improve net protein balance in malnourished adult ESRD patients on maintenance HD [132]. A number of detailed metabolic studies and prospective randomized trials provide convincing direct or indirect evidence that GH treatment can improve not only nutritional biomarkers and lean body mass, but also inflammation, lipid profile, erythropoiesis,

and cardiovascular status in maintenance dialysis patients [109]. Beneficial effects of GH on net muscle protein balance are believed to be due to a combination of simultaneous improvements in protein synthesis and protein breakdown, suggesting a potential involvement of multiple mechanisms, such as direct actions of GH on protein synthesis and indirect actions through activation of IGF-I [40]. Although recombinant hGH is currently not commonly used to treat PEW in patients with CKD, these hormones represent a potentially effective intervention in this vulnerable patient population [40,133–136]. In the OPPORTUNITY Trial, a randomized clinical trial examining the efficacy and safety of once-daily subcutaneous injections of hGH (vs placebo) in adult hypoalbuminemic maintenance HD patients, treatment with hGH improved certain cardiovascular risk factors, including reduced total fat mass, increased serum high-density lipoprotein cholesterol and transferrin, and reduced serum high-sensitivity C-reactive protein and possibly homocysteine. OPPORTUNITY was terminated early after randomizing only 712 of the planned 2500 patients. In this smaller group of patients the administration of hGH did not reduce mortality, cardiovascular events or improve nutritional factors or quality of life [133]. In another study investigating the potential additive anabolic effects of hGH plus human IGF-I (hIGF-I) in HD patients, a short-term administration of a moderate dose of hGH plus hIGF-I (vs hIGF-I alone) significantly improved whole-body protein synthesis [134].

### Appetite stimulants

Pharmacologic agents that may stimulate appetite include megestrol acetate, dronabinol, cyproheptadine, melatonin, thalidomide, and ghrelin. Most of these drugs, however, have not been systematically studied in HD patients with PEW. Megestrol acetate, a progesterone derivative, can stimulate appetite and induce small increases in serum albumin and weight in HD patients [137]. Ghrelin is an orexigenic peptide released primarily from the stomach that increases appetite and adjusts both short- and long-term energy balance. In addition to its direct orexigenic effects (as aforementioned), ghrelin administration has been shown to inhibit sympathetic nerve activity and inflammatory response and improve left ventricular function and exercise capacity [109], making it a potentially promising drug candidate for the treatment of PEW in patients with ESRD.

### Antiinflammatory agents

Antiinflammatory agents could be considered for the treatment of PEW in CKD patients who are persistently inflamed despite appropriate interventions for potential sources of inflammation (e.g., infections,

fluid retention) [138]. Such agents include the drugs that have pleiotropic antiinflammatory effects and anticytokine agents [138,139]. Commonly used drugs in CKD such as statins, vitamin D receptor agonists, and angiotensin-converting enzyme inhibitors have been shown to possess antiinflammatory properties [138,139]. Although these drugs are seldom prescribed with the sole intention of reducing inflammation and are in fact not as effective as antiinflammatory agents, they are often considered valuable adjuvants in strategies aiming at reducing systemic inflammation in CKD patients [138,139]. Currently, there are only limited studies on the effects of anticytokine agents on nutritional parameters in uremic patients. In a small pilot study of 22 HD patients, administration of IL-1 receptor antagonist resulted in significant improvements in C-reactive protein and IL-6 levels, along with an increase in serum albumin, serum prealbumin, and lean body mass [140]. Similarly, the administration of etanercept, a TNF receptor antagonist, showed positive effects on serum albumin and prealbumin levels in HD patients [141]. Pentoxifylline, a nonspecific phosphodiesterase inhibitor, is another anticytokine agent that inhibits the production of TNF, IL-6, and IL-10 [142]. In patients with CKD the administration of pentoxifylline has been shown to improve protein breakdown along with an incremental anabolic effect when combined with a balanced amino acid mixture [143]. In a recent randomized controlled trial of 36 HD patients, pentoxifylline administration for 4 months significantly reduced serum concentrations of inflammatory biomarkers [144], suggesting its therapeutic potential for PEW in CKD. It should be noted, however, that the antiinflammatory treatment with these biological anticytokine agents may increase the risk of infections and other complications such as severe allergic reactions. Therefore large-scale studies are needed to examine the efficacy and safety of anticytokine therapies as nutritional interventions in CKD patients.

### **Antimyostatin agents**

Pharmacological inhibition of myostatin has been suggested as a new therapeutic choice for PEW in CKD [106]. In CKD mice, subcutaneous injections of an antimyostatin peptibody (a chimeric peptide-Fc fusion protein) suppressed circulating inflammatory cytokines and reversed the loss of body weight and muscle mass [145]. These effects were associated with decreased muscle protein degradation and increased protein synthesis, as well as enhanced satellite cell function and IGF-I signaling [145]. In a recent study using a rodent CKD model, myostatin inhibition via a neutralizing peptibody suppressed the proliferation of

newly identified fibro/adipogenic progenitor cells and muscle fibrosis [146]. In humans, myostatin-targeted therapeutic approaches have been studied in early stage clinical trials in a variety of conditions, including genetic disorders, cachexia syndromes, and disuse, and demonstrated increase in muscle mass and functional measures of muscle [147–150]. However, it remains unknown whether these antimyostatin agents can exert similar beneficial effects for PEW in patients with CKD.

## **Summary and conclusion**

There is an increasing incidence and prevalence of CKD worldwide with poor outcomes and profound economic implications. CVD is the most common cause of death in patients with CKD. Conventional risk factors of CVD and mortality (obesity, serum cholesterol, and homocysteine) may paradoxically have a protective effect in ESRD patients suggesting that nutritional status has an overriding effect on survival [151–153]. Surveys using classic measures of nutritional status indicate that approximately 20%–75% of CKD patients show evidence for malnutrition or wasting [154]. Results from the National Health and Nutrition Examination Survey III confirm that renal function is independently associated with PEW [155]. CKD patients have clinical and biochemical evidence of PEW such as anorexia, loss of lean body mass, decreased serum albumin, prealbumin and IGF-I, impaired response to anabolic hormones, ineffective amino acid utilization for protein synthesis, and increased energy expenditure, especially in the setting of coexistent inflammation. The pathogenesis of PEW in CKD is multifactorial and involves a complex interplay of several factors or mediators that directly or indirectly affect nutrient intake, protein metabolism, and energy balance, which may vary in importance depending upon the nature of the inciting stimulus or event that occurs during the evolution of the disease. It is clear that factors, such as anorexia with inadequate food intake, acidemia due to advanced renal failure, and nutrient losses into dialysate in dialysis patients, play a contributory role. More recently, identified mediators of PEW include proinflammatory cytokines, insulin resistance, abnormal neuroendocrine signaling, altered physiology of adipokines, and abnormal skeletal muscle protein kinetics. A clear understanding of the pathogenic mechanism and cellular signaling pathways is important to institute individualized, targeted interventions for PEW in CKD.

## Introduction

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality in persons with chronic kidney disease (CKD) and accounts for over 50% of deaths in patients with end-stage kidney disease (ESKD) [1]. CKD is a powerful risk state for the development of coronary artery disease (CAD), leading the National Kidney Foundation and the American College of Cardiology/American Heart Association (ACC/AHA) to recommend that CKD be considered a CAD risk equivalent [2,3]. While traditional cardiovascular risk factors, such as smoking, hypertension, diabetes, dyslipidemia, and older age, are more prevalent in patients with CKD than the general population, a number of nontraditional risk factors, including oxidative stress and inflammation, protein-energy wasting (PEW), anemia, fluid overload, and arterial calcification, may also contribute to the increase in morbidity and mortality in this population (Box 14.1) [3].

In this chapter, we discuss the epidemiology of cardiovascular risk factors, including hypertension, dyslipidemia, diabetes, left ventricular hypertrophy (LVH), and PEW, in the setting of kidney disease. In addition, we review strategies to prevent and manage coronary disease and heart failure (HF) in dialysis patients as well as patients with CKD stages 3 and 4. The care of kidney transplant recipients, diagnostic cardiovascular testing, the use of specific biomarkers, and other CVD outcomes, such as stroke, peripheral artery disease, and pericardial and valvular diseases, are beyond the scope of this chapter (see Chapter 33 for information about nutritional management of kidney transplant recipients). Details on the

mechanisms of PEW, inflammation, uremia, and oxidative and carbonyl stress are covered in Chapters 7, 12, and 13.

## Cardiovascular risk factors

### Hypertension

**Epidemiology:** Hypertension is both a cause and result of CKD and its prevalence increases as glomerular filtration rate (GFR) declines [4].

### Dialysis

#### Epidemiology

Depending on the population studied, nearly 85% of dialysis patients have hypertension [5,6]. Hypertension is more common at the time of dialysis initiation due to the presence of volume overload. There is also a high prevalence of intradialytic hypotension and sometimes intradialytic hypertension (approximately 10%). Most studies have shown that there is a “U-” shaped relationship between predialysis blood pressure (BP) and both CVD outcomes and all-cause mortality [7–10]. Possible explanations for the association of low BP with adverse outcomes include that low BP may reflect the severity of CVD and PEW [11]. Ambulatory blood pressure monitoring (ABPM) may be an option to guide clinical decision-making in dialysis patients since pre- and postdialysis BP measures vary significantly. In addition, data suggest a closer association between ABPM and clinical outcomes [6,12]. Recent literature has emphasized the importance of assessing volume and the relation of excess volume in promoting both hypertension and adverse outcomes in both CKD and dialysis [13,14].

Trials and recommendations

The BP in dialysis pilot study randomized 126 dialysis patients to assess the feasibility and safety of a standardized predialysis systolic BP (SBP) of 110–140 mmHg (intensive arm) versus 155–165 mmHg (standard arm) [15] and evaluate its effect on LVH. On average, patients in the intensive arm had a 10 mmHg lower SBP compared to the control arm (146 vs 156 mmHg) but had a greater risk of recurrent hospitalization, vascular access thrombosis, and intradialytic hypotension, despite an increase in postdialysis weight. There was no change in the primary outcome of LVH between groups. While the 2005 Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines suggest pre- and postdialysis BP goals of <140/90 and <130/80 mmHg, respectively (level C recommendation based on expert opinion), several more recent guidelines have refrained from specific BP targets in dialysis patients [16]. Although metaanalyses and some trials have suggested a benefit with the use of antihypertensive agents in dialysis patients [17,18], both because of heterogeneity and small sample sizes, data supporting specific target BP values and preferred antihypertensive agents remain weak. In contrast to a report from the 2015 European Renal and Cardiovascular Medicine Working Group [19], the Kidney Disease: Improving Global Outcomes (KDIGO) consensus committee concluded that there were insufficient data to develop a new guideline on BP management in dialysis patients [20].

CKD stages 1–4

Epidemiology

The pathogenesis of hypertension in CKD is multifactorial with the major mechanisms thought to be salt

and water retention as well as activation of the renin–angiotensin–aldosterone system (RAAS). Hypertension is an independent risk factor for the progression of CKD as well as the development of CVD and BP management targets both these complications.

Trials and recommendations

Individual RCTs as well as metaanalyses of RCTs have demonstrated that the use of RAAS inhibitors reduces the progression of kidney disease in patients with and without diabetes [21–25], particularly in those with proteinuria [23,26,27]. The combined use of angiotensin-converting enzyme inhibitors (ACE-I) and angiotensin receptor blockers (ARBs) decreases proteinuria to a greater extent than either drug alone [28,29]; however, in studies of individuals with mild proteinuria, dual blockade was associated with an increased risk of worsening of kidney function, including progression to ESRD without improvement in CVD outcomes or mortality [28,29]. The large VA NEPHRON-D trial randomized patients with type 2 diabetes, albuminuria, and a GFR between 30 and 89 mL/min per 1.73 m<sup>2</sup> to combination therapy with an ACE-I and ARB or ACE-I and placebo [30]. The trial was terminated early due to an increased incidence of adverse events, including acute kidney injury (AKI) and hyperkalemia in the group receiving dual RAAS blockage.

Over the last decade a number of guidelines on the management of BP in persons with CKD have been published. The 2012 KDIGO BP guideline suggested a BP target of <130/80 mmHg in both diabetes and nondiabetes in individuals with >30 mg/d of albuminuria (or equivalent) and 140/90 mmHg in those with <30 mg/d [31]. The greater the levels of proteinuria, the stronger the grade of

the recommendation [32]. On the other hand, the European Society of Hypertension/European Society of Cardiology (ESH/ESC) guidelines [33] and the JNC-8 panel members [34] recommended a target of <140/90 for persons with CKD irrespective of the degree of albuminuria. The SPRINT trial randomized 9361 adults  $\geq 50$  years with SBP 130–180 mmHg and elevated cardiovascular risk to goal SBP <120 versus <140 mmHg. Patients with diabetes, stroke, HF, proteinuria >1 g/d, polycystic kidney disease, eGFR <20 mL/min per 1.73 m<sup>2</sup>, and ESRD were excluded [35]. The study showed a 27% lower all-cause mortality and 25% lower cardiovascular end point. Similarly, a subgroup analysis of those with CKD in SPRINT (mean GFR 48 mL/min per 1.73 m<sup>2</sup> and median albuminuria 81 mg/g) demonstrated that intensive BP control resulted in nearly 20% lower risk of all-cause and 28% lower risk of CVD-related mortality [36]. A large metaanalysis of 18 trials of BP lowering in patients with stages 3–5 CKD demonstrated a lower risk of mortality with intensive therapy [37]; however, specific target BP goals could not be conclusively recommended because of significant heterogeneity in the studies included.

After the publication of the SPRINT the ACC/AHA 2017 Hypertension guidelines redefined the hypertension as BP  $\geq 130/80$  mmHg and recommended antihypertensive treatment to a BP goal of <130/80 mmHg in patients with CKD and others at increased cardiovascular risk [38]; this is similar to the KDIGO recommendation in 2012. The 2018 ESH/ESC guidelines recommend an SBP of 130–139 mmHg and diastolic BP of 70–79 mmHg for patients with CKD [39]. Little data exist in individuals with CKD stage 5, nondialysis as to the optimal BP target.

## Dyslipidemia

Abnormalities in lipoprotein metabolism are common in patients with kidney disease and may vary depending on the stage of kidney disease [40] (Table 14.1). Total cholesterol levels may be normal or low in patients with advanced kidney disease, the latter possibly perhaps reflecting PEW [41].

## Dialysis

### Epidemiology

Hemodialysis (HD) and peritoneal dialysis (PD) patients have increased levels of triglycerides and lipoprotein-a compared to patients with milder forms of kidney dysfunction, with PD patients, potentially reflecting constant dextrose absorption, having particularly atherogenic lipid profiles. The linear association between increasing levels of cholesterol and CAD-related mortality seen in the general population is less evident in patients with kidney disease. Observational studies have demonstrated a “reverse epidemiology” between total cholesterol levels and mortality in dialysis patients, that is, increased risk at low cholesterol levels. In a study of over 12,000 HD patients receiving lipid-lowering therapies, persons with total cholesterol <100 mg/dL had nearly four times the risk of death compared to those with levels between 200 and 250 mg/dL (Fig. 14.1) [42–45]. There is evidence that malnutrition and chronic inflammation may be effect modifiers on this association [44] with low cholesterol being a surrogate for poor nutritional status.

### Trials and recommendations

Two trials, 4D (Die Deutsche Diabetes Dialyse) study, in which HD patients with diabetes and high-serum low-density lipoprotein (LDL) were treated with atorvastatin or placebo, and AURORA (A study to evaluate the Use of Rosuvastatin in subjects On Regular hemodialysis: an Assessment of survival and cardiovascular events) in which HD patients were treated with rosuvastatin or placebo, failed to demonstrate a significant reduction in mortality or other CVD outcomes despite reduction in LDL levels [46,47]. The SHARP (Study of Heart and Renal Protection) trial evaluated the efficacy of simvastatin and ezetimibe compared with placebo in lowering cardiovascular outcomes in 9270 patients with CKD and 3023 patients receiving dialysis [48]. Results for the dialysis subgroup in SHARP do not appear dissimilar from those

TABLE 14.1 Lipid profiles across the spectrum of kidney disease as compared to the general population.

seen in 4D or AURORA, showing no significant benefit, although given the absence of a statistical interaction between CKD and dialysis, and a benefit in the entire population, the overall interpretation remains open to debate (Fig. 14.2). Based on the results of the 4D, AURORA, and the dialysis subgroup of SHARP, the 2013 KDIGO guidelines do not recommend initiating statin therapy in persons undergoing HD but suggest continuing them if started prior to the initiation of dialysis. There are no clinical trials focusing on PD, although results from SHARP in the subgroup of participants receiving PD suggest a possible benefit [48].

### CKD stages 1–4

#### Epidemiology

Dyslipidemia is very common in CKD, occurring in over 50% of patients with nephrotic range proteinuria [49]. Like the dialysis population, the presence of malnutrition and inflammation may alter the association between total cholesterol levels and mortality [50].

#### Trials and recommendations

There is significant controversy surrounding timing of therapy, target LDL level, utility of rechecking levels once medication has been initiated and dose of drug to be used. The best evidence for the use of statins in the prevention of CVD events comes from the SHARP trial in addition to post hoc analysis of trials of the general population. Among 6247 participants with CKD not on dialysis included in SHARP, there was a reduced incidence of CVD mortality, nonfatal myocardial infarction (MI), and stroke (9.5% vs 11.9%) among patients treated with simvastatin and ezetimibe compared to placebo [51]. A metaanalysis of 26 trials that included 25,017 participants with stage 3 or 4 CKD reported a significant reduction in proteinuria, all-cause and cardiovascular mortality, and nonfatal CVD outcomes compared to placebo, without an effect on progression of CKD [52].

In 970 diabetic participants with GFR between 30 and 60 mL/min/1.73 m<sup>2</sup> in the Collaborative Atorvastatin Diabetes Study trial, there was a 42% reduction in major CVD events among patients taking atorvastatin compared to placebo [53]; however, atorvastatin did not reduce mortality similar to the mortality results in SHARP. In the JUPITER trial (Rosuvastatin to Prevent Vascular Events in Men and Women with Elevated C-Reactive Protein), a secondary analysis of patients with CKD (GFR <60 mL/min per 1.73 m<sup>2</sup>) demonstrated a 45% reduction in first cardiovascular events and all-cause mortality among men and women with LDL-cholesterol (LDL-C) <130 mg/dL and elevated C-reactive protein (CRP) with rosuvastatin compared to placebo [54].

More recently, a number of drugs targeting proprotein convertase subtilisin/kexin type 9 (PCSK-9) have been studied in the prevention of CVD events. The Long-term Safety and Tolerability of Alirocumab in High Cardiovascular Risk Patients with Hypercholesterolemia Not Adequately Controlled with Their Lipid Modifying Therapy (ODYSSEY LONG TERM) trial enrolled 174 patients with a GFR <60 mL/min per 1.73 m<sup>2</sup> at baseline [55]. In this group, treatment with alirocumab was associated with 62% reduction in LDL-C levels compared to 8% elevation in the placebo arm. While existing data suggest that the benefit afforded by PCSK-9 inhibitors may extend to the earlier stages of CKD [56]. Further studies are needed prior to recommending routine use of PCSK-9 inhibitors in persons with advanced kidney disease.

Based on the abovementioned data, the 2013 KDIGO guidelines recommend screening all persons with CKD not on dialysis using a lipid panel and treating those older than 50 years of age with a statin [57]. In addition, the guidelines recommend treating all patients younger than 50 years of age with known CAD, stroke, and diabetes with a statin. Unlike prior KDOQI guidelines that recommend lowering LDL-C to <100 mg/dL [58], the current KDIGO guidelines do not recommend routine

follow-up monitoring of lipids in patients taking moderate- or high- intensity statins, defined as daily atorvastatin 20 mg, rosuvastatin 10 mg, simvastatin 40 mg, pravastatin 40 mg, fluvastatin 80 mg, or pitavastatin 2 mg. The treatment of hypertriglyceridemia in CKD is limited by a lack of trial data demonstrating a benefit.

### Diabetes mellitus

Diabetes is the most common cause of kidney failure in the United States and is present in approximately 40%–50% of incident dialysis patients [59]. The risk of developing kidney failure among diabetics has declined over the last 20 years, possibly reflecting better glycemic control and use of kidney-protective medications that block the RAAS [59].

### Dialysis

#### Epidemiology

Diabetes is an independent risk factor for all-cause mortality, cardiovascular mortality, and nonfatal CVD events in dialysis patients [60,61].

#### Trials and recommendations

Post hoc analysis from 4D found that HbA1C values >8% were associated with a twofold increase in sudden cardiac death compared to HbA1C values <6% [62]. However, data from other large observational studies of dialysis patients are conflicting, with some not revealing an association between HbA1C levels and survival in dialysis patients [62–64], while others

report a monotonic increase in mortality with higher HbA1C levels, especially in nonanemic patients [65,66]. It is important to recognize that uncontrolled diabetes can worsen retinopathy and diabetic neuropathy and increase the risk of vascular complications, thus necessitating a fine balance to avoid both hyperglycemia and hypoglycemia in this high-risk population. While not perfect, HbA1C seems a reasonable approximation of serum glucose levels in the absence of marked anemia [67]. The 2005 KDOQI guidelines (although outdated) for therapy reflected American Diabetes Association (ADA) recommendations with a target HbA1C of <7% [16]. However, there are no RCTs to support tight control in this population, and we would suggest individual decision-making and tolerance of higher targets in many individuals so as to avoid the risk of hypoglycemia [68]. Extrapolating from studies in populations with high comorbid disease burden, we feel that, in many patients, higher targets are reasonable because of increased risks versus benefits.

### CKD stages 1–4

#### Epidemiology

In patients with CKD, diabetes significantly increases the risk of mortality and adverse CVD outcomes [69]. It had previously been thought that the natural progression of diabetic kidney disease in almost all patients would be microalbuminuria progressing to macroalbuminuria and subsequently to a reduction in GFR. However, it is being increasingly

recognized that a significant percentage of patients with presumed diabetic kidney disease develop a sustained decline in GFR without ever developing high levels of albuminuria [70,71].

### **Trials and recommendations**

A number of observational studies have shown that sustained hyperglycemia is a risk factor for the development of moderately elevated urine albumin excretion [72–74], and that a reduction of HbA1C level is associated with a significant decrease in albuminuria and microvascular complications [75,76]. The benefit of strict glycemic control on macrovascular and CVD outcomes is less clear [77]. While some evidence suggests a reduction in cardiovascular mortality among patients with type 1 diabetes mellitus (DM) who maintain near normoglycemia (HbA1C approximately 7%) [78], other trials have shown that intensive glucose control is instead associated with increased mortality and significantly more episodes of hypoglycemia [79,80].

In persons with type 2 DM, results of the ADVANCE Trial showed a 9% reduction in microalbuminuria, 30% reduction in macroalbuminuria, and a 65% reduction in the risk of ESKD with intensive glucose control (achieved HbA1C 6.5%) compared to standard therapy (achieved HbA1C 7.3%) [81]. However, other studies have not shown similar results. Data from the ACCORD (Action to Control Cardiovascular Risk in Diabetes) study that randomized over 10,000 patients who had type 2 diabetes for at least 10 years to an intensive glucose control regimen (target HbA1C <6%) versus regular control (target HbA1C <7%) found an increased risk of all-cause mortality and cardiovascular mortality in the intensive control group [82]. These results question whether tight control is indicated in patients with long-standing diabetes (such as CKD patients). Of note, however, ACCORD excluded participants with frequent or recent serious hypoglycemic events and those with a serum creatinine level of more than 1.5 mg/dL [80]. Critically, post hoc analysis of ACCORD suggests that concurrent intensive BP control and intensive glycemic control may be associated with increased risk of adverse outcomes [83]. The ADA currently recommends maintaining the HbA1C level below 7% but suggests less stringent control in some patients with type 2 diabetes, specifically those with significant comorbid conditions and a reduced life expectancy [84]. Lifestyle and exercise have also been shown to decrease risk of progressive kidney function decline as shown in the Look AHEAD study [85]. In this trial, patients randomized to increased exercise demonstrated slower loss of GFR compared to standard therapy arm.

Sodium–glucose cotransporter-2 (SGLT-2) inhibitors have been approved for use alone or in combination with

other agents in individuals with type 2 diabetes [86]. The best evidence of SGLT-2 inhibitor for kidney protection use comes from the CREDENCE (Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation) trial. In CREDENCE, 4401 individuals with type 2 diabetes, severely elevated albuminuria, and eGFR 30–<90 mL/min per 1.73 m<sup>2</sup> received 100 mg of canagliflozin or placebo added to renin–angiotensin–aldosterone blockade and baseline diabetic therapy [87]. The risk of the primary outcome (composite of ESRD, doubling of serum creatinine, or death from kidney or cardiovascular causes) was reduced by 30% with canagliflozin treatment. Currently, there are no data supporting the initiation of SGLT-2 inhibitors in individuals with GFR <30 mL/min per 1.73 m<sup>2</sup>, including dialysis patients, although, in CREDENCE and other SGLT-2 inhibitor trials, these agents were not routinely discontinued when eGFR dropped below 30 mL/min per 1.73 m<sup>2</sup> [88]. Further studies are needed to ensure its safety and efficacy in

persons with advanced kidney disease and in persons without diabetes.

Glucagon-like peptide-1 receptor agonists (GLP-1 receptor agonists) are a class of antihyperglycemic drugs that are not cleared by the kidney and, therefore, may confer a lower risk of hypoglycemia compared to insulin in this high-risk population. AWARD-7 was a multicenter trial comparing once-weekly dosing of the GLP-1 receptor agonist dulaglutide to insulin glargine in 577 participants with diabetes and stages 3 and 4 CKD [89]. Treatment with dulaglutide was associated with a lower HbA1C at 26 weeks (primary outcome) and was associated with 2.5 times lower hypoglycemic events compared with insulin glargine. In the LEADER trial, 9340 participants with type 2 diabetes and high cardiovascular risk were randomly assigned to receive liraglutide (a GLP-1 receptor agonist) or placebo, added to standard diabetes treatments. Liraglutide therapy resulted in 22% lower composite kidney outcome (albuminuria, doubling of serum creatinine, ESKD, and mortality) [90] in addition to lowering risk of CVD events in persons with CKD [91].

### **Left ventricular hypertrophy**

LVH is a common complication in all stages of CKD, including dialysis. It represents an adaptation on the part of the myocardium to pressure and fluid overload and is also considered a traditional risk factor for adverse CVD outcomes.

### **Dialysis**

#### **Epidemiology**

The prevalence of LVH as detected by echocardiography among incident dialysis patients is reported to

be as high as 75% [92–94]. Dialysis patients are host to a number of modifiable risk factors that potentiate the development of LVH, including hypertension, volume overload states, arteriovenous fistulas, and anemia. LVH is an independent risk factor for mortality and adverse CVD outcomes like HF [95–97].

### **Trials and recommendations**

Evidence-based management guidelines for LVH in ESRD and CKD are lacking due to the absence of RCTs. Due to association of LVH with mortality and CV outcomes, the 2005 KDOQI guideline recommended that an echocardiogram be performed in all patients at the initiation of dialysis once patients have achieved dry weight [16]; however, there is no statement of clinical interventions in response to the results of the echocardiogram. Targeting achievement of dry weight and controlling BP are also recommended with indirect evidence in support of these recommendations [98]. Control of hypertension via afterload reduction and optimizing volume status in dialysis patients have shown to be associated with some improvement in LVH. In the Frequent Hemodialysis Network Daily Trial, frequent in-center HD was associated with a composite outcome of lower all-cause mortality and LV mass [99]. However, correction of anemia with erythropoietin has not been shown to prevent or cause regression on LVH in randomized trials [100,101].

### **CKD stages 1–4**

#### **Epidemiology**

The prevalence of LVH increases as kidney function declines going from 32% when the GFR is  $>60$  mL/min per  $1.73$  m<sup>2</sup> to nearly 75% when the GFR is  $<30$  mL/min per  $1.73$  m<sup>2</sup> [93,102]. LVH is independently associated with worsening kidney function, progression to dialysis, and development of cardiovascular outcomes [103,104].

### **Trials and recommendations**

Despite a number of potentially modifiable risk factors for the development of LVH, success in prevention and regression of established LVH has been limited. The PRIMO trial was a double-blind placebo-controlled trial among 227 patients with CKD and mild-to-moderate LVH. Treatment with paricalcitol did not alter LV mass index or improve parameters of cardiac function in this CKD population [105]. Similar to dialysis, correction of anemia in CKD stages 3 and 4 has not been shown to prevent progression of LVH or worsening of kidney function [106,107] and in some studies has been associated with worsening of cardiac outcomes [108]. Maintaining BP targets and utilization of BP agents as outlined earlier is recommended.

### **Protein-energy wasting, malnutrition, and inflammation**

**Epidemiology:** The complex syndrome of nutritional deficiency, muscle wasting, and chronic inflammation that occur in persons on dialysis has been given a number of names, including uremic cachexia, malnutrition–inflammation atherosclerosis syndrome, or malnutrition–inflammation complex. The International Society of Renal Nutrition and Metabolism (ISRNM) proposed a common nomenclature and diagnostic criteria for these alterations in the context of CKD. PEW was proposed to denote concurrent losses in protein and energy stores, with cachexia being regarded as only the end stage. PEW may be diagnosed in the presence of at least three of the following four signs: [1] low serum albumin, transthyretin (prealbumin), or cholesterol; [2] decreased body mass (low body mass index, unintentional weight loss, or decreased body fat); [3] reduced muscle mass (low midarm muscle circumference or area, decreased creatinine appearance, or recent history of loss of muscle mass); and [4] unintentional low energy or protein intake [109]. The prevalence of PEW varies with the population studied. In a large metaanalysis of 97 studies with nearly 18,000 patients, the reported prevalence was between 60% and 82% among those with AKI, between 11% and 54% for CKD stages 3–5, and up to 80% in patients on maintenance dialysis [110]. PEW in CKD and dialysis patients is associated with impaired quality of life, greater morbidity, and increased cardiovascular mortality, mortality from infection, and total mortality [111]. Hypoalbuminemia, a surrogate marker for malnutrition, has been associated with increased cardiovascular mortality in dialysis patients [112–114]; however, mortality associated with hypoalbuminemia may reflect chronic inflammation rather than exclusively malnutrition [115,116]. Markers of chronic inflammation, such as elevated CRP and interleukin-6, have been associated with increased morbidity and mortality [117–119]. In addition, sarcopenia and lower fat mass, commonly seen in dialysis patients, are associated with increased mortality and morbidity [120,121].

**Trials and recommendations:** Scoring systems such as Malnutrition–Inflammation Score [122] and the Objective Score of Nutrition on Dialysis [123] have been developed to identify and predict dialysis patients at risk of increased mortality and morbidity, but further studies are needed to see if any interventions to improve these scores will affect clinical outcomes. Low-protein diets (0.6–0.8 g/kg per day) have been recommended for persons with CKD to slow progression of GFR decline while on the other hand much higher dietary protein is recommended for patients on dialysis [124]. Data suggest a potential benefit of oral

protein supplementation and parenteral protein supplementation in dialysis patients on lean body mass and serum albumin levels [125]. There is also emerging observational data that these interventions may be associated with lower hospitalization and mortality [126,127]. No large trials have demonstrated a benefit of nutritional supplementation in reducing mortality, CVD outcomes in dialysis patients. The ongoing Health Effects of Oral Protein Supplements in Hemodialysis Patients trial is an open-label cluster randomized trial evaluating the effectiveness of oral intradialytic nutritional supplements on mortality and should provide answers to some of these questions in late 2020 [128].

### **Other risk factors**

Smoking, obesity, and lack of exercise are other traditional risk factors for CVD in CKD patients. Smoking is associated with adverse cardiovascular outcomes in all stages of CKD [129] and also may promote progression of CKD [130,131]. Smoking cessation is associated with a decrease in the risk of CVD outcomes in dialysis patients [132], and all patients, regardless of CKD status, should be encouraged to quit smoking. Obesity, independent of diabetes, is a risk factor for the development and progression of CKD and development of CVD in the earlier stages of CKD [133,134]. Overweight and obese patients in the early stages of CKD should be encouraged to lose weight (details of nutrition and weight loss in CKD are discussed in Chapter 40), and all patients with CKD should be encouraged to exercise at a moderate intensity for 30 minutes most, if not all, days per week [16]. Patients who are not currently physically active should start at very low levels and durations and gradually progress to this recommended level.

## **Management of CVD**

### **Coronary artery disease**

#### **Epidemiology**

CAD is a common cause of CVD morbidity and mortality among patients with kidney disease [1]. The prevalence of CAD among incident dialysis patients may be as high as 40% [135]. The incidence of acute coronary syndromes (ACS) among dialysis patients in the United States Renal Data System (USRDS) Dialysis Morbidity and Mortality study was 29 per 1000 patient years, with risk factors for ACS being similar to the general population—older age, male sex, diabetes, and known CAD [136]. In the same study, outcomes for dialysis patients with MI were extremely poor with 50% and 80%, 1- and 3-year mortality rates,

respectively. Even after revascularization with coronary artery bypass grafting (CABG), mortality rates are exceedingly high with arrhythmias being the cause of death in approximately 25% of these patients [137].

### **Therapy of ischemic heart disease**

#### **Medical therapy**

Most trials evaluating prevention and treatment of CAD excluded patients with advanced CKD/ESRD and most trials, including participants with advanced CKD, do not report subgroup analysis based on CKD stage [138]. Therefore most recommendations are based either on observational studies in CKD, subgroup analyses of patients with earlier stages of CKD from general population studies, or extrapolation from trials in the general population [139]. As discussed in the sections earlier, the benefit of preventative measures aimed at lowering the risk of CVD, such as aggressive lipid lowering, and blood glucose control remains equivocal in patients with advanced CKD, especially those on dialysis. Despite the adverse prognosis associated with MI in the setting of CKD, standard therapeutic strategies are less rigorously applied to these patients [140]. This may be due to a combination of poor outcomes despite appropriate therapy and an aversion to include patients with advanced CKD in trials given the higher risk of adverse outcomes with some interventions.

Retrospective analysis of patients enrolled in the Dialysis Outcomes and Practice Patterns Study suggested no benefit on mortality but a lower risk of MI in patients on dialysis who were prescribed aspirin [141]. Post hoc analysis from the PLATO trial, which randomized patients with ACS to either ticagrelor or clopidogrel, demonstrated that the ischemic benefit of ticagrelor over clopidogrel was greatest in persons with both diabetes and CKD [142]. No trials have exclusively addressed antiplatelet therapy for secondary prevention of CAD in CKD/ESRD patients, but post hoc analysis of the Hypertension Optimal Treatment (HOT) study demonstrated that the addition of aspirin resulted in fewer adverse CV events; however, this was not statistically significant, possibly due to small sample size [143]. In the absence of active gastrointestinal bleeding, risks and benefits of aspirin therapy should be assessed for all CKD and dialysis patients, especially those with vascular disease, diabetes, and the elderly. The increased bleeding risk in dialysis patients at risk of CVD but without ACS necessitates an individualized approach.

In patients with stable angina, ACE-I and ARBs have similar benefit in CKD subgroups compared to those without CKD [144,145]. However, ACE/ARB should be used with additional caution in patients

with advanced CKD given the increased risk of hyperkalemia. Beta-blockers have only been studied to a limited extent in CAD populations with CKD, but there is evidence to suggest that they confer a mortality benefit among CKD patients with CAD, including patients with HF [146,147]. Data also suggest that beta-blockers may reduce all-cause and sudden cardiac death in dialysis patients with ischemic heart disease [148]. Statin therapy is discussed earlier.

### Revascularization

Observational data and older clinical trial data suggest that clinical outcomes for CKD patients with ACS are better after revascularization compared to medical management alone [149–151], resulting in a recommendation in 2011 from the American College of Cardiology Foundation/American Heart Association that an early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is reasonable in patients with mild and moderate CKD [152]. A patient-level metaanalysis of individuals enrolled in trials compared percutaneous coronary intervention (PCI) versus CABG suggested that CABG significantly reduces the risk of subsequent MI and revascularization without affecting survival in these patients [153]. However, there were few patients with advanced CKD enrolled in this study. Using data from 21,981 patients on maintenance dialysis in the USRDS registry, investigators compared outcomes between patients who received initial coronary revascularization with either CABG or PCI between 1997 and 2009 [154]. The study demonstrated that CABG compared with PCI was associated with significantly lower risks for both death and the composite of death or MI, but is vulnerable to residual confounding. In another analysis of USRDS data, investigators showed that while in-hospital mortality among dialysis patients undergoing CABG was higher than with PCI, long-term survival and repeat coronary revascularization was lower with CABG [154]. Taken together, the observational data support the hypothesis that CABG may be superior to PCI for long-term survival in patients receiving dialysis, with the caveat that these data are biased by patients healthy enough to undergo CABG.

In a retrospective propensity matched analysis of patients with advanced CKD and ACS, therapy with drug-eluting stents (DES) did not significantly improve death, MI, or target vessel revascularization compared with bare-metal stents (BMS) at 2 years of follow-up [155] (Table 14.2). A recent large metaanalysis of 31 studies (5 randomized) with 91,817 participants with CKD and CAD suggests significantly fewer all-cause mortality, cardiovascular mortality, MI, target vessel revascularization, and stent thrombosis events with DES compared to BMS with even a lower stent thrombosis rates with second-generation DES [156].

Similar to patients without CKD who have stable CAD, or are asymptomatic, the role of revascularization among similar patients with CKD remains unclear. The ISCHEMIA-CKD trial randomized 777 patients with stable ischemic heart disease (CAD) and eGFR <30 mL/min per 1.73 m<sup>2</sup>, including those in dialysis to optimal medical therapy (OMT) versus revascularization plus OMT [157]. Results show that the primary outcome, death or MI at 2.3 years, occurred in 36.4% of the routine invasive group compared with 36.7% of the OMT group ( $P = .95$ ), therefore suggesting that routine invasive therapy failed to reduce its incidence [158].

### Heart failure

#### Epidemiology

HF is among the more frequently diagnosed CVDs in the CKD population. The bidirectional pathophysiological interaction between abnormalities in kidney (sodium and fluid handling) and cardiac function (decreased cardiac output, venous congestion, and reduced perfusion) is often referred to as cardiorenal syndrome. Both the prevalence and incidence of HF are high in patients with kidney disease, especially those with kidney failure [159]. Over 40% of patients receiving dialysis have prevalent HF [1,61], with recent data from the USRDS also demonstrating a prevalence of HF in CKD patients aged 66 and older of approximately 26%, compared to 6% among patients without CKD [159]. Rates of hospitalization and death due to HF are also significantly higher in dialysis patients than in those without kidney disease

TABLE 14.2 Two-year clinical outcomes.

Outcome	DES (n = 431)	BMS (n = 431)	Rate difference (95% CI)	P
Death	39.4% (170/431)	37.4% (161/431)	2.1% (−4.3–8.5)	.5
MI	16.0% (69/431)	19.0% (82/431)	−3.0% (−8.2–2.1)	.5
TVR	13.0% (56/431)	17.6% (76/431)	−4.6% (−9.5–0.3)	.06

[1]. In a large metaanalysis of patients with HF, those with moderate–severe kidney disease or any kidney disease had 2.3 and 1.5 times risk of death compared to those without kidney disease, respectively [160].

Treatment of heart failure

Volume control by ultrafiltration is an extremely important component of HF therapy in dialysis patients [161]. The maintenance of euvolemia can be challenging, with factors like intradialytic hypotension precluding adequate fluid removal. In such patients, limited evidence suggests that switching to more frequent or longer dialysis may improve fluid balance and cardiac function [162]. PD may also represent an underutilized option. Diuretics are used as first-line therapy in the treatment of volume overload and hypertension in persons with kidney disease. Among persons with decompensated HF and kidney disease, a stepped-up diuretic regimen to achieve adequate urine flow has shown to be as efficacious and potentially safer than the use of extracorporeal fluid removal therapies [163] unless there is concomitant kidney failure needing dialysis. As with persons without

kidney disease, the use of diuretics, ACE-I or ARB and beta-blockers forms the mainstay of treatment of persons with kidney disease and HF in the setting of reduced ejection fraction (EF) (Fig. 14.3).

Most studies of HF management have unfortunately excluded patients with advanced CKD. As a result, the vast majority of the literature is extrapolated for populations with either moderate (CKD 3a) kidney disease or those without kidney disease. No trials of ACE-I or ARBs focusing on patients with HF and CKD have been performed. Data from subgroup analysis of larger trials of ACE-I, including the CONSENSUS (Cooperative North Scandinavian Enalapril Survival Study) and the SOLVD Treatment (Studies of Left Ventricular Dysfunction Treatment) trial, demonstrate consistent evidence of better outcomes with ACE-I therapy in patients with HF (or LV systolic dysfunction after MI) and CKD stage 3 [164–166]. The Valsartan in Heart Failure Trial randomized 5010 patients with NYHA classes II to IV HF to receive the ARB valsartan or placebo in addition to optimal HF therapy, which included ACE inhibition in >90% of patients. Of them, 58% had a GFR <60 mL/min per

1.73 m<sup>2</sup> and 8% had dipstick positive proteinuria. The beneficial effect of valsartan on first morbid events was similar in those with and without CKD and proteinuria [166].

Similarly, the beneficial effect of aldosterone blockers in patients with CKD has been demonstrated in post hoc analysis of larger trials. In both the TOPCAT (Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist Trial) and the RALES (Randomized Aldactone Evaluation Study) trials, spironolactone therapy was associated with a lower relative risk of outcomes across all eGFR categories, including mortality and HF-related hospitalizations [167,168]. However, in advanced CKD stages, there is a concern for increased risk of hyperkalemia, AKI, and mortality thus warranting closer monitoring. The use of newer potassium binding agents may allow the use of continued RAAS blockage with advanced CKD, which in the past may have been discontinued due to hyperkalemia. In a small trial of patients receiving dialysis, the use of spironolactone was safe and tolerable but did not change diastolic parameters compared to placebo [169].

Finerenone is a newer nonsteroidal mineralocorticoid receptor antagonist that was studied in the Mineralocorticoid Receptor Antagonist Tolerability Study, a dose-finding study in approximately 1000 patients with worsening HF with reduced EF and type 2 DM and/or CKD [170]. All doses of finerenone were associated with a reduction in plasma N-terminal pro–brain natriuretic peptide concentration, while the secondary outcome, including a composite of death, cardiovascular hospitalization, or emergency department visit for worsening HF, occurred less frequently in two highest doses of finerenone-treated patients despite the fact that this phase 2 study was not designed to

detect statistical significant differences. Larger studies in more advanced CKD are currently underway [171].

In the MERIT-HF trial, randomized nearly 4000 patients with symptomatic HF and EF <40% (of which nearly 1500 persons had GFR <60 mL/min per 1.73 m<sup>2</sup>), treatment with metoprolol was associated with a greater risk reduction in mortality compared to placebo among persons with CKD than in those without CKD [172]. Similar results were also seen in a study of bisoprolol in persons with kidney disease [173]. Carvedilol is the only beta-blocker to have been studied in a randomized trial in dialysis patients with HF and dilated cardiomyopathy and demonstrated a significant reduction in mortality compared with placebo (Fig. 14.4) [174].

Recently, SGLT-2 inhibitors, including empagliflozin, canagliflozin, and dapagliflozin, have all shown to reduce the risk of HF-related hospitalization in persons with diabetes and at least stage 3a CKD [175–177]. Until more data are available, caution must be exercised with their use in CKD stage 4. Digoxin should be used with extreme caution in dialysis patients given the potential for serious side effects. Furthermore, observational data have suggested increased mortality with the use of digoxin in this population, although admittedly these studies may be limited by indication bias [178].

## Conclusion

Persons with CKD, including those treated with dialysis, have a significant burden of CVD. Aggressive risk factor modification and treatment of CVD should be considered in the care of this population, particularly those with nondialysis CKD, keeping in mind these individuals are also at a higher risk of adverse

outcomes from the interventions themselves, stressing the role of individualized care. Further clinical studies of CVD should focus on and include patients with advanced kidney disease.

## Introduction

Nutritional management and dietary intake have a major impact on kidney health and longevity. Among the macronutrients a large body of evidence has shown that increased dietary protein engenders changes in renal hemodynamics, kidney function, and kidney morphology. It has also been shown that various individual amino acids may have differential effects on kidney function, according to their site of metabolism. There has also been growing interest in the impact of dietary protein sources on kidney health outcomes, with more salutary benefits observed with plant-based, low-fat dairy, and white meat sources as opposed to red meat sources. Multiple concurrent mechanisms may mediate the protein- and amino acid-induced changes in kidney function and morphology, including endocrine factors [e.g., growth hormone (GH), insulin-like growth factor-1 (IGF-1), glucagon, renin-angiotensin-aldosterone, dopamine, atrial peptides] or local mediators [e.g., eicosanoids, nitric oxide (NO)]. To date, the direct impact of dietary carbohydrate and fat intake on kidney function and structure has not been well studied, but emerging evidence suggests potential associations between the dietary intake of these macronutrients, including amount and type, with the development and progression of chronic kidney disease (CKD). In the nonkidney disease population, certain dietary patterns [e.g., Dietary Approaches to Stop Hypertension (DASH), Mediterranean diets] have been endorsed by clinical practice guidelines given their favorable effects on hypertension, diabetes,

cardiovascular risk, and survival and long-term sustainability. As examination of dietary patterns provides a more comprehensive and synergistic assessment of nutritional status in lieu of single nutrients, an increasing number of studies have also examined the impact of the DASH and Mediterranean diets on the development and progression of CKD.

Distinction should be made between intentional versus unintentional modulation of dietary intake, as these two entities have differential effects on kidney health outcomes. While prescribed low-protein diets in nourished adults have been shown to ameliorate CKD progression, unintentional reductions in dietary protein intake due to protein-energy wasting may lead to acute physiologic changes in renal hemodynamic, kidney function, urinary concentration, and sodium handling. Furthermore, early exposure to malnutrition may have long-term adverse sequelae, and growing research has shown that maternal malnutrition and isocaloric dietary protein restriction even in the pre- and peri-conception periods as well as over the course of pregnancy have an important bearing on kidney growth and/or function in later life.

In this chapter, we review the current evidence regarding (1) the effects of dietary protein and amino acids, other macronutrients (e.g., carbohydrate, fat), and dietary patterns on CKD outcomes; (2) pathways mediating the effects of macronutrient intake on kidney parameters; (3) the impact of protein energy-wasting malnutrition on kidney health outcomes; and (4) the impact of maternal nutritional status on the development and progression of CKD.

## Impact of nutritional status on kidney function

### Dietary protein intake on kidney function and structure

A large body of evidence has shown that dietary protein and/or amino acid intake leads to changes in renal hemodynamics, kidney function, and kidney morphology (Fig. 15.1). In 1906, one of the first reports of the effects of dietary protein intake on kidney status showed that rats that were fed higher-than-usual amounts of dietary protein intake developed *increased kidney weight* over time [1]. Subsequent studies in both animals [2–8] and humans [9] have also shown that higher protein and/or amino acid loads result in *increased kidney size*.

Numerous studies have also shown that protein and/or amino acid ingestion also leads to *functional changes of the kidney*, including *increased renal blood flow* and *glomerular filtration rate* (GFR) in animals [10–13] and humans [14–19]. For example, in a study of 37 healthy adults who were administered mild, moderate, and large protein meals (defined as 0.55, 1.08, and 1.35 g/kg, respectively), there was a positive dose-dependent relationship between the amount of oral protein intake and GFR ascertained by inulin clearance and renal blood flow defined by *p*-aminohippurate clearance [20]. Similarly, in a study of eight healthy adults who underwent intravenous administration of balanced amino acids solution at varying doses, increasingly higher infusion rates were associated with a dose-related rise in GFR and renal blood flow [21]. In another study of eight healthy adults who were given a low- and high-protein diet for 6 days each, GFRs were observed to be higher on the high-protein diet and acutely rose within 1 hour and peaked at 2 hours following the protein load [22].

In diabetic patients, it has also been suggested that high protein intake may be more detrimental to patients with diabetes than those without diabetes. In a study of 12 diabetic patients versus 9 controls who underwent an overnight fast followed by an amino acid infusion, a more exaggerated increase in GFR and renal plasma flow with amino acid infusion was observed in the diabetic versus nondiabetic patients [23]. Conversely, it has been suggested that high-protein parenteral and/or enteral nutrition should be considered during an acute kidney injury (AKI) event to promote glomerular perfusion and faster recovery of the nephron (i.e., increased circulating amino acid levels in the blood dilate afferent arterioles of the glomeruli and increase renal perfusion and intraglomerular pressure) and to provide adequate nutritional support particularly during critical illness, such that a CKD patient on a low-protein diet should be temporarily transitioned to high-protein diet during the AKI period [24].

The onset of protein-induced alterations in renal hemodynamics that occur immediately after a protein and/or amino acid load may persist in the short term; however, the long-term effects of high protein loads on kidney health are less clear. Continuous *short-term intake* (i.e., days to weeks) of a high-protein diet appears to have similar effects on renal hemodynamics as that of acute postprandial kidney responses to high protein loads [22,25], although some studies [26–28] have not observed changes in GFR or renal blood flow. In healthy adults, it has also been suggested that variations in age [27], activity level, and/or nutritional status may result in differential effects of short-term high dietary protein loads on kidney function [29]. With respect to *long-term effects*, randomized trials [30,31], observational studies, and meta analyses [32–36] have suggested that high dietary protein intake may lead to

**FIGURE 15.1** Impact of changes in macronutrient and amino acid intake on renal hemodynamics. Among the macronutrients, dietary protein intake directly affects postprandial renal hemodynamics. There is a dose-dependent increase in renal hemodynamics after protein intake. Varying sources of dietary protein may have differential effects on kidney function: animal protein, especially red meat intake, may stimulate renal hemodynamics, whereas plant protein has a lesser effect. As components of protein, amino acids may directly affect renal hemodynamics, whereas peripherally metabolized amino acids, such as branched-chain amino acids, may have no relationship to renal hemodynamics. Carbohydrate and fat intake may have indirect effects on kidney function (i.e., hyperglycemia, metabolic syndrome, obesity), but further research in this area is needed.

increased glomerular hyperfiltration and subsequent kidney dysfunction [29,35,37]. Yet in the scientific and lay communities, the long-term impact of high dietary protein intake on the risk of CKD and end-stage renal disease (ESRD) remains unclear, while more recent data and discussions imply that high protein intake may cause harm to kidney health in the long term [35,38,39].

### Protein sources, amino acids, and kidney function

Growing evidence suggests that varying sources of dietary protein intake have disparate effects on kidney function and health [40–42]. While dietary protein from red meat sources has been associated with adverse effects on kidney function, dietary protein from plants, dairy products, and white meat may have a protective effect on kidney health. However, further research is needed to determine the impact of specific dietary protein sources on short- and long-term kidney functions.

The ingestion of various individual amino acids may also have differential effects on kidney function (Table 15.1), according to their site of metabolism [43–45]. Most amino acids are metabolized in the liver, whereas branched-chain amino acids (BCAAs) (e.g., valine, leucine, isoleucine) are catabolized in peripheral organs, particularly in skeletal muscle. Hence, while the group of amino acids that are preferentially metabolized in the splanchnic region contribute to alterations in postprandial renal hemodynamics, amino

acids that are peripherally metabolized such as BCAAs do not appear to lead to glomerular hyperdynamic stimulation [46]. Indeed, several studies suggest that supplemented BCAAs may have beneficial effects on kidney health, including slowed progression of kidney disease due to diminished glomerular hyperdynamic stimulation [47,48]. These less stimulatory effects on renal hemodynamics by BCAAs versus other amino acids may be explained by the metabolic features of BCAAs. Indeed, humans with excess intake of BCAAs may have postprandial adaptations in which they do not experience change in renal hemodynamics. BCAAs taken in excess of their requirements are catabolized via reversible transamination to the branched-chain  $\alpha$ -keto acids (BCKAs), followed by irreversible oxidative decarboxylation of BCKAs by the dehydrogenase enzyme complex (BCKD) [49]. The importance of efficient BCAA catabolism may be in part due to the fact that excess BCAAs or BCKAs due to inborn errors of BCAA metabolism are toxic to the central nervous system [49]. However, BCKD distribution is not consistent across organs, and the kidney shows relatively low capacity for BCKD compared to other organs, including muscle [50,51]. Indeed, it has been confirmed that there is no significant renal uptake of BCAAs in the postabsorptive phase [52]. In normal subjects, kidneys excrete mostly glutamine (58% of total amino acid excretion) as well as proline, citrulline, and phenylalanine, while it releases serine (37% of total amino acid output), plus taurine, threonine, tyrosine, ornithine, lysine, and arginine into the circulation. Interestingly, chronically insufficient kidneys are also not responsible

TABLE 15.1 The effects of individual amino acids and/or amino acid categories on renal hemodynamics across studies.

Amino acid(s)	Human subjects <sup>a</sup>	Dogs <sup>b</sup>	Rats
<b>Glucogenic amino acids</b>			
Arginine	GFR↑, RPF↑		GFR↑, RPF↑
Glycine	GFR↑, RPF↑	GFR↑ (given intravenously)	
Proline	GFR↑, RPF↑	GFR↑	
Cysteine	GFR↑, RPF↑	GFR→	
Methionine	GFR↑, RPF↑		
Serine	GFR↑, RPF↑	GFR→	
Alanine	Renal hemodynamics→	GFR↑	
BCAA	Renal hemodynamics→		
Threonine		GFR↑	
Glutamic acid		GFR↑	
Aspartic acid		GFR↑	
Valine		GFR↑	

<sup>a</sup>Administered intravenously.

<sup>b</sup>Administered via stomach tube.

↑, Increase; →, not changed. BCAA, Branched-chain amino acid; GFR, glomerular filtration rate; RPF, renal plasma flow.

for BCAA excretion [52]. Furthermore, BCAAs (particularly leucine) not only function as a protein substrate but also as an anabolic substance promoting stimulation of protein synthesis in skeletal muscle, liver, and adipose tissues [53] and inhibition of protein breakdown [54].

### Pathways mediating the impact of dietary protein and amino acid intake on kidney health

The mechanisms underlying protein- and amino acid–induced changes in kidney function and morphology may be related to endocrine or local mediators, as well as intrarenal mechanisms as described in Table 15.2.

#### Humoral mediators

##### Growth hormone and insulin-like growth factor-1 axis

GH and IGF-1 have been implicated as major hormonal mediators in the renal response to protein loads, including alterations in kidney size and structure

and increased renal blood flow and GFR. Most of GH's effects are mediated by growth factors induced by GH in target organs and tissues such as the kidney, as well as the liver, adipose tissue, heart, and skeletal muscle [55]. Among these, IGF-1 is the most physiologically relevant and most extensively studied GH-induced growth factor [56].

GH and IGF-1 levels rise following protein and/or amino acid ingestion [17,57,58], and GH and IGF-1 both directly impact kidney structure, as well as glomerular and tubular function. For example, mice with greater representation of GH genes demonstrate renal hypertrophy, manifested as increased kidney size and weight, glomerular hypertrophy, mesangial proliferation, and glomerulosclerosis [59,60]. In studies of patients with acromegaly, limited data have shown evidence of glomerular hypertrophy [61], whereas other studies have shown marked increases in GFR and renal plasma flow following GH and IGF-1-mediated reductions in renal vascular resistance [62–64]. In addition, acromegalic states are associated with increases in total body water and sodium retention and subsequent

TABLE 15.2 Pathways mediating the impact of dietary protein and amino acid intake on kidney status.

Mediator category	Factor	Mechanism	Effects on kidney status
Endocrine	Growth hormone/insulin-like growth factor-1 axis	Disproportionate renal growth	Renal hypertrophy (increased kidney size/weight, glomerular hypertrophy, mesangial proliferation, glomerulosclerosis)
		↓ Renal vascular resistance	Changes in glomerular function (↑ renal blood flow, ↑ GFR)
		Soft-tissue enlargement, ↑ ENaC-dependent sodium transport	Body fluid retention (sodium and water expansion, ↑ sodium reabsorption)

6-keto PGF<sub>1α</sub>, 6-Keto prostaglandin F<sub>1α</sub>; cAMP, cyclic adenosine monophosphate; COX, cyclooxygenase; GFR, glomerular filtration rate; mRNA, messenger RNA; NOS, nitric oxide synthase; PE-PLA<sub>2</sub>, phosphatidylethanolamine-specific phospholipase A<sub>2</sub>; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; PGF<sub>2α</sub>, prostaglandin F<sub>2α</sub>; PRA, plasma renin activity levels.

soft-tissue enlargement [65,66], independent of effects by the renin–angiotensin–aldosterone system or atrial natriuretic peptides (ANP) [67]. Patients with acromegaly have also shown alterations in mineral bone disease metabolism, including mild hyperphosphatemia, heightened intestinal calcium absorption, and increased tubular calcium reabsorption [68,69], which may potentially have ill effects on kidney function and structure. Notably, mice transgenic for IGF-1 do not develop glomerulosclerosis and have less severe glomerular hypertrophy [59,70]. Thus it is conceivable that GH or GH-induced increased IGF-1 levels, with the existence of functional GH or IGF-1 receptors, might be a mediator of the renal response to protein and amino acids.

However, it bears mention that the role of GH and IGF-1 in the renal response to protein and/or amino acid intake has been questioned in some studies showing that protein-related increases in renal plasma flow and GFR occurred prior to or in the absence of increased GH levels. Furthermore, GH-deficient patients have also exhibited renal vasodilation following amino acid infusion [22,71,72]. Hence, further research is needed to clarify the contribution of GH and IGF-1 to dietary protein-related alterations in kidney structure and function.

### Glucagon

Glucagon is not only a glucose regulatory hormone but is also considered a key player in amino acid metabolism and nitrogen excretion following dietary protein intake or amino acid administration. After a dietary protein load or an amino acid infusion, there is an increase in glucagon secretion [73–75]. Concurrent with the rise in plasma glucagon levels, there is a dose-dependent increase in GFR that correlates with glucagon concentrations [17].

While the role of glucagon has been strongly suspected as a mediator of glomerular hyperfiltration, other studies have shown contrary findings. For example, some studies have not observed significant correlations between plasma glucagon concentrations and the rise in GFR [76]. Other research have also shown that GFR changes following an amino acid infusion were not correlated with glucagon in and of itself but were instead correlated with the glucagon-to-insulin ratio [77]. Some studies examining the mechanisms of glucagon-induced increases in GFR have also revealed that there are simultaneous rises in plasma glucagon and cyclic adenosine monophosphate (cAMP) levels that are required for glomerular hyperfiltration. These glucagon-induced changes in GFR were significantly and positively correlated with simultaneous changes in plasma cAMP levels, largely derived from the liver, and in the urine-to-plasma urea level ratio [78]. Other

studies have found that increased peripheral blood glucagon levels after protein meal ingestion did not result in higher GFRs [79,80], and infusion of glucagon without coinfused cAMP nor cAMP alone were not associated with increases in GFR [79]. These latter observations suggest that the simultaneous effects of dietary protein-induced increases in plasma glucagon and extracellular cAMP are responsible for rises in GFR following a protein or amino acid load.

### Renin–angiotensin–aldosterone system

It is well established that dietary protein regulates both the synthesis and release of renin [81–85], as well as renin–angiotensin–aldosterone activity in modulating glomerular hemodynamics [86]. Renin may have greater implications as a mediator of the long-term effects of protein consumption on kidney health, as opposed to the acute renal response to protein intake. Indeed, most studies indicate that plasma renin activity and angiotensin II levels do not acutely rise during protein ingestion [72,87,88]. In contrast, studies have shown that subacute and chronic alterations in dietary protein intake modulate plasma renin activity. For example, a study in seven healthy adults showed plasma renin activity levels were significantly higher after 5 days of high dietary protein intake (i.e., 2.0 g/kg/day) [89]. These observations have been corroborated in other studies of normal rats [82,83], healthy adults [90], and in patients with kidney failure [91]. In terms of the latter, experimental animal models examining changes in renal messenger RNA (mRNA) levels suggest that high protein loads contribute to increased plasma renin activity. Normal rats that were fed a high-protein diet (i.e., comprising 50% protein) demonstrated greater increases in renin mRNA levels in comparison to rats fed a standard protein diet (i.e., comprising 24% protein) [84]. Similarly, in a study of subtotal nephrectomized rats, renal renin mRNA levels were higher in the high-protein diet group (i.e., comprising 40% protein, administered for 7 days following 7 days of low-protein diet intake) compared to those in the low-protein diet group (i.e., comprising 6% protein, administered for 14 days) [81].

### Dopamine

The kidneys synthesize dopamine from circulating or filtered decarboxylated L-3,4-dihydroxyphenylalanine (L-DOPA), the major source of renal dopamine production [92], independent of renal innervation. Although sodium intake and intracellular sodium are thought to be the major determinants of the renal tubular synthesis/release of dopamine [93,94] a high protein load [95,96] or feeding [97] may increase urinary dopamine levels, which may be secondary to an increase in L-DOPA synthesis.

Increased levels of dopamine act on the kidney via two families of cell-surface receptors, D<sub>1</sub>- and D<sub>2</sub>-like receptors. Dopamine largely acts via D<sub>1</sub>-like receptors to augment renal vasodilation, renal blood flow [98–100], and urinary volume and ion excretion, including natriuresis [101,102]. In contrast, the effects via D<sub>2</sub>-like receptors are dependent upon the state of nerve activity and may be associated with an increase in GFR [103,104]. An acute increase in the amount of protein ingested with a single meal or a chronic increase in dietary protein intake over several days raises brain tyrosine levels and stimulates catecholamine synthesis, including dopamine [105]. Thus protein and/or amino acid loads have effects on kidney function via both intrarenal dopamine and innervation-related dopamine pathways.

### Atrial peptides

Previous studies examining ANP as a potential mediator of the renal response to protein ingestion have shown mixed findings. It is well known that ANP increases GFR by promoting direct vasodilatory effects on the afferent arterioles, thereby allowing more blood to enter the glomerulus for ultrafiltration [106,107]. However, there are sparse data supporting a role for ANP in protein-related increases in GFR. Some research have shown that plasma ANP levels were elevated following a high-protein meal (i.e., 1.0–1.5 g of protein/kg) [108], while other studies have demonstrated that plasma ANP levels were elevated only after the first hour after a high-protein meal ingestion (i.e., 10.0 g of lean beef/kg) [109] or were in fact decreased or remained unchanged after high-protein consumption (i.e., 1.0 g of protein/kg) [110,111]. Furthermore, among these studies, it was found that plasma ANP levels were not significantly associated with creatinine clearance after a protein meal [109].

### Local mediators

#### Eicosanoids

In animal models, protein-induced augmentation of GFR and renal blood flow are accompanied by increases in glomerular production of eicosanoids [83,112,113]. Eicosanoids are locally acting bioactive signaling lipids that regulate a broad range of homeostatic and inflammatory biologic processes [114,115]. Synthesis of these local mediators occurs through enzymatic or nonenzymatic free radical mechanisms following the oxidation of arachidonic acid [116]. As the first step of eicosanoid biosynthesis, phospholipase, including phosphatidylethanolamine-specific phospholipase A<sub>2</sub> (PE-PLA<sub>2</sub>), phosphatidylcholine-specific phospholipase A<sub>2</sub>, and phosphatidylinositol-4,5-bisphosphate-specific phospholipase C play an important role in

increasing the levels of free arachidonic acid from its esterified stored form. Eicosanoids are then derived from free arachidonic acid thorough one of three pathways, cyclooxygenase (COX), lipoxygenase, and cytochrome P450 pathways, or via nonenzymatic free radical mechanisms.

Some studies have demonstrated the subacute and chronic effects of a high-protein diet (i.e., 2 weeks [117] or 6 weeks [118]) on glomerular eicosanoid production in normal rats as well as rats with glomerular disease. These data have demonstrated the modulating effect of dietary protein on glomerular eicosanoid production, specifically stimulation of glomerular synthesis of prostaglandin E<sub>2</sub>, prostaglandin F<sub>2α</sub>, and 6-keto prostaglandin F<sub>1α</sub>, eicosanoids generated via the COX pathway, in both normal and glomerular diseased rats. This dietary protein-induced modulation of glomerular eicosanoid production was also observed irrespective of the presence or absence of arachidonic acid, indicating that dietary protein augmented glomerular COX activity. Another study examining intraglomerular mechanisms underlying dietary protein-induced production of eicosanoids showed that this may be mediated by augmentation of COX levels and activity, coupled with enhanced activity of PE-PLA<sub>2</sub> [118].

#### Nitric oxide

NO is a well-known vasodilator produced by the vascular endothelium via the enzyme endothelial NO synthase (eNOS). Dietary protein and amino acid intake and other dietary factors are known to modulate NO production [119–121]. Low dietary protein intake results in reduced NO production via decreased expression of the enzymes and essential cofactors needed for its synthesis [122]. For example, L-arginine and citrulline are substrates for eNOS in the synthesis of NO in almost all mammalian cells [123–125]. Furthermore, citrulline is a precursor of L-arginine and is converted from L-citrulline to L-arginine by the kidneys in the production of NO [126,127]. In turn, NO is involved in numerous physiologic processes that impact both acute and chronic regulation of kidney function and systemic blood pressure [128–135]. With respect to renal hemodynamics, in animal models, the inhibition of NO synthesis (i.e., via administration of structural analogs of L-arginine) was shown to prevent or blunt the effects of amino acid stimulation of renal vasodilation, increased renal blood flow, and increased GFR [136–140].

### Dietary carbohydrate intake and kidney function

The direct impact of dietary carbohydrate on kidney function has not been well studied, although emerging

evidence suggest a potential association with the development of CKD [141,142]. Indeed, a growing number of experimental animal models and epidemiologic studies have examined the short- and long-term implications of amount of dietary carbohydrate intake and/or dietary carbohydrate type on kidney function, which have shown mixed findings (Table 15.3).

In one experimental study of dogs, dietary carbohydrate and fat intake were not associated with acute (i.e., postprandial) nor subacute (i.e., weekly) alterations in renal hemodynamics [143]. Yet findings from a randomized trial of 163 overweight/obese adults without underlying diabetes or kidney disease suggest that dietary carbohydrate type and amount may have short-term implications on kidney function [144]. In this study, participants were administered four types of diets, combinations of high versus low glycemic index diets and high versus low carbohydrate diets (defined by proportion of total energy intake) over a 5-week period, and concurrent receipt of low glycemic index and low carbohydrate diets had additive effects on increasing GFR while maintaining constant body weights. These data signal the potential short-term benefits of low glycemic index diets (i.e., comprising complex carbohydrates, fiber, and other beneficial nutrients) upon kidney health. With respect to the carbohydrate amount, it is possible that the short-term rise in GFR observed with lower carbohydrate consumption may have been due to the substitution of dietary protein for dietary carbohydrate in the prescribed diets.

Limited studies that have examined the long-term impact of carbohydrate type and amount upon the development of incident CKD have also shown conflicting findings. In one observational study, 2600 healthy adults underwent assessment of dietary glycemic index ascertained by food frequency questionnaires and were followed for up to 5 years [145]. While cross-sectional analyses showed that the highest quartile of dietary glycemic index intake was associated with higher prevalence of moderate CKD [defined as an estimated GFR (eGFR) < 60 mL/min/1.73 m<sup>2</sup>], longitudinal data did not support an association with incidence of kidney disease. In a more recent epidemiologic study of the Korean Genome Epidemiology Study, those in the highest two quartiles of dietary carbohydrate density intake (i.e., proportion of total energy take) ascertained by 24-hour dietary recall had a higher risk of developing CKD (defined as the composite of an eGFR ≤ 60 mL/min/1.73 m<sup>2</sup> and development of proteinuria) compared to those in the lower quartiles of intake [146]. Potential explanatory mechanisms of the relationship between higher dietary carbohydrate intake and CKD include the development of metabolic abnormalities (i.e., higher waist-to-hip ratios and HOMA-IR), inflammation, oxidative stress, and alterations in gut microbiota. Future studies are needed to determine the longitudinal impact of dietary carbohydrate intake amount and type upon kidney health, as well as the precise mechanisms underlying the link between dietary carbohydrate intake and kidney function.

## Dietary fat intake and kidney function

There has been growing interest in the impact of dietary fat intake on metabolic health and downstream kidney disease. Several studies in animals and humans have supported long-term associations between higher dietary fat intake and alterations in kidney structure and function (Table 15.3). It has been hypothesized that prolonged metabolic perturbations (i.e., persistent hyperglycemia, obesity, inflammation) induced by a high-fat diet may contribute to kidney damage over time.

Experimental animal models have shown that long-term intake of high-fat diets over an 8- to 12-week period leads to renal fat accumulation with concomitant changes in kidney structure and function. In these studies the amount of dietary fat ranged from 15% [147] to 30% [148] to 60% [149] of total energy intake and was derived from saturated fat sources, including lard, beef tallow, and coconut oil. Different types of dietary fat have been noted to have varying effects on kidney health. For example, in a study of spontaneously hypertensive rats that were fed five different types of edible oils (e.g., fish, canola, palm, olive, and soybean) versus placebo for 13 weeks, rises in blood pressure as well as glomerulosclerosis, glomerular enlargement, and glomeruli loss were prevented among those that received fish, canola, and palm oils and were attenuated in those that received olive and soybean oils [150]. Notably, the most favorable effects were observed with fish oil administration (source of  $n-3$  polyunsaturated fatty acids, eicosapentaenoic and docosahexaenoic acids), followed by canola and palm oils, and finally olive and soybean oils. In another study of rats that were administered four types of high-fat diets (e.g., soybean oil, canola oil, lard + egg yolk, and canola oil + lard + egg yolk), those that were fed soybean or canola oil had greater preservation of glomerular size and number [151]. Finally, in a study of rats across varying ages that were fed 5%-lipid-enriched diets with three different sources of fat (e.g., canola oil, fish oil, and butter) versus a control diet, those that were fed any of the lipid-enriched diets had faster onset of increased proteinuria than controls [152]. While age-related decline in GFR and renal blood flow were observed in all lipid-enriched diet groups, deterioration in these parameters was most marked in those receiving butter and fish oil.

Epidemiologic studies have also signaled a relationship between higher dietary fat intake and CKD [153]. In a study of 3348 women from the Nurses' Health Study, greater intake of animal fat was significantly associated with higher risk of albuminuria [154]. In addition, higher intake of total fat, saturated fat, and animal fat was each associated with higher risk of

eGFR decline. Similarly, in a study of 19,246 men and women from the Reasons for Geographic and Racial Differences in Stroke cohort, greater intake of saturated fat was associated with higher risk of albuminuria [155]. However, in this study, total fat nor other types of dietary fat were not associated with risk of albuminuria or eGFR decline.

With respect to the short-term implications of dietary fat, limited research to date has not identified an association between higher fat consumption and adverse CKD outcomes [156]. In an experimental study of Sprague Dawley rats that were fed high-fat and/or high-sugar diets (e.g., excess lard, sucrose, or a combination of lard + sucrose) over a 4- and 8-week period, while there was a significant increase in weight and abdominal fat over these time periods, while no changes in kidney mass were observed [156]. In another study of Sprague Dawley rats that were fed a high-fat diet versus standard chow over a 6-week period, while the high-fat diet was found to increase adiposity and renal mass, there was no evidence of early kidney injury ascertained by urinary and plasma biomarkers (urine to protein creatinine ratio, plasma cystatin C) nor renal histology. These limited observations suggest that short-term metabolic changes (i.e., moderate hyperglycemia, inflammation) induced by a high-fat diet are not sufficient to cause kidney damage, nor does a ketogenic, high-fat diet contribute protection to the kidney [157]. Similarly, dietary fat and dietary carbohydrates have not been observed to cause acute or short-term (i.e., postprandial or over weeks) changes in renal hemodynamics [143].

## Dietary types and kidney function

While renal nutrition has historically focused on single nutrients (i.e., macronutrients, micronutrients, or other bioactive substances present in food), there has been growing interest in studying dietary patterns (i.e., comprehensive examination of nutrients, foods, food groups, combinations, as well as their variety, frequency, and quantity in habitual diets) that may be more predictive of overall kidney health status and CKD risk (Table 15.4) [158,159]. Indeed, using a "food synergy" approach/strategy, which is based on the assumption that in most cases food substances have additive or synergistic effects on health, may provide more meaningful and pragmatic guidance to patients and the public health community in promoting sustainable dietary behaviors that promote kidney health.

## Dietary Approaches to Stop Hypertension diet

The DASH diet is a dietary pattern that has been endorsed by the US National Institutes of Health for

TABLE 15.4 Selected studies of dietary types and kidney function.

the prevention and management of hypertension. The DASH diet is rich in fruits, vegetables, whole grains, and low-fat dairy products but notably is not a low-protein diet; it also includes fish, poultry, beans, and nuts, whereas sugar-sweetened foods, red meat, and fats are limited [160]. The DASH diet has been recommended by multiple clinical practice guidelines for disease prevention and health promotion given its favorable impact on not only hypertension [161,162], but also type 2 diabetes [163,164], cardiovascular disease and stroke [165], and survival [166].

Large population-based studies have demonstrated that greater adherence to the DASH diet is associated with favorable renal outcomes. Greater adherence to the DASH diet has been associated with lower risk of incident CKD and/or CKD progression in the Nurses' Health Study [33]; participants from the Healthy Aging in Neighborhoods of Diversity across the Life Span cohort at the poverty level [167]; the Tehran Lipid and Glucose Study [168]; and the Atherosclerosis Risk in Communities cohort [169]. The individual components of the DASH diet, including its sources of

protein (e.g., plant-based foods, low-fat dairy) and accompanying nutrients, may be the drivers of better kidney health trajectory [42]. Potential mechanisms by which greater adherence to the DASH diet may reduce incident CKD and CKD progression include reductions in blood pressure, attenuation of dietary acid load, and improvement in endothelial function [169].

### Mediterranean diet

Similar to the DASH diet, the Mediterranean diet is balanced, flexible, has long-term sustainability, and supports lifestyle changes (i.e., increased physical activity), and has been recommended as a beneficial and sustainable dietary pattern for CKD patients [170]. The Mediterranean diet's components include greater consumption of fruits, vegetables, olive oil, legumes, and cereals; moderate-to-high intake of fish; moderate intake of dairy and wine; and low intake of red meat [171].

A growing number of studies have examined the association between the Mediterranean diet [172] and kidney outcomes, which have shown mixed findings.

In a clinical trial of community-dwelling adults in Spain from the Prevención con Dieta Mediterránea study, participants randomized to a Mediterranean diet + additional virgin olive oil, Mediterranean diet + additional mixed nuts, and a low-fat control diet showed similar improvements in kidney function after 1 year [173]. Yet a number of observational studies have shown that greater adherence to the Mediterranean diet is associated with lower risk of incident CKD and/or kidney function decline among children in the KIDMED cohort [174]; participants in the ATTICA study [175]; and adults in the Northern Manhattan and Tehran Lipid and Glucose cohorts [176,177].

### Impact of protein-energy wasting on kidney function

Protein-energy wasting is a widespread public health problem that contributes to the morbidity and mortality in populations in which it is prevalent [178]. The abovementioned evidence has shown that a low-protein diet due to intentional reduction in dietary protein intake has a favorable impact on kidney function trajectory. In contrast, unintentional reductions in dietary protein intake likely due to protein-energy wasting have been linked with unfavorable kidney health outcomes, including acute reductions in GFR and renal plasma flow (Table 15.5), urinary concentrating defects, and acid–base disturbances as described next (Table 15.6 and Fig. 15.2).

### Protein-energy wasting and kidney function

Short-term reductions in dietary protein intake have been shown to decrease GFR and renal plasma flow in normal subjects. In a clinical study of healthy young women and men that compared the effects of low dietary protein intake (defined as 0.3 g of protein/kg) with moderate dietary protein intake (defined as 1.0 g of protein/kg/day) over a 2-week period in the same subjects [179], low dietary protein demonstrated a fall in GFR as measured by inulin clearance and *p*-aminohippurate clearance, as well as effective renal plasma flow. Notably, these two diets were isocaloric and were designed to maintain constant body weights.

Protracted reductions in protein and caloric intake may result in protein-energy wasting with downstream alterations in kidney function (Table 15.5). Studies in both developed and developing countries have shown that both adults and children with protein and calorie malnutrition experienced acute changes in renal function that were reversed with repletion [178]. For example, in a study of 32 children from Jamaica whose ages ranged from 7 to 21 months old, those with protein and calorie malnutrition demonstrated reductions in GFR and renal plasma flow; following repletion and refeeding with protein, improvements in GFR and renal plasma flow were observed [180]. In another study of 10 adults with protein-energy wasting admitted to a metabolic ward in Colombia, patients underwent assessment of kidney function before and after protein repletion. These patients demonstrated

marked reductions in both GFR and *p*-aminohippurate clearance, increased following protein repletion [181].

In a more recent study of 1572 South Koreans from the prospective KoreaN Cohort Study for Outcomes in Patients with CKD cohort, lower dietary protein intake was associated greater decline in kidney function over time [182]. These associations were attenuated to the null following adjustment for markers of protein-energy wasting, suggesting that malnutrition may have been on the causal pathway between lower dietary protein intake and kidney function decline in this cohort.

### Protein-energy wasting and renal hemodynamics

In adult subjects, severe protein-energy wasting not only leads to decreased GFR but also reduced renal plasma flow [181,184–187]. As noted earlier, among the 10 adults with protein-energy wasting admitted to a metabolic ward in Colombia who demonstrated marked reductions in renal plasma, normalization of renal hemodynamics was observed following protein repletion [181]. In another study of four adults with malnutrition in a concentration camp of Belsen after

World War II, reduced renal plasma flow was observed in subjects with malnutrition and edema, whereas normal renal plasma flow was observed in those with malnutrition but without edema [184]. However, in another study of 11 adults with “under-nutrition” (i.e., lesser degree of malnutrition than the abovementioned studies), only 1 out of 11 subjects demonstrated renal plasma flow falling below 100 mL/min [185]. Studies of protein-energy wasting in children have more consistently demonstrated reductions in renal plasma flow and improvement following protein repletion [180,188,189]. Given that the renal hemodynamic alterations in the abovementioned studies were largely improved following dietary protein repletion, it is likely that these reductions in renal plasma flow reflect a physiologic adaptation to severe protein-energy wasting.

Possible mechanisms by which protein-energy wasting contributes to an acute decline in renal plasma flow and GFR have been theoretically well-defined, but the actual regulation of filtration remains less clear [181]. The driving force for GFR is the balance of hydrostatic and oncotic pressure across the glomerular membrane. Notably, varying durations and severity of protein-energy wasting may lead to differential

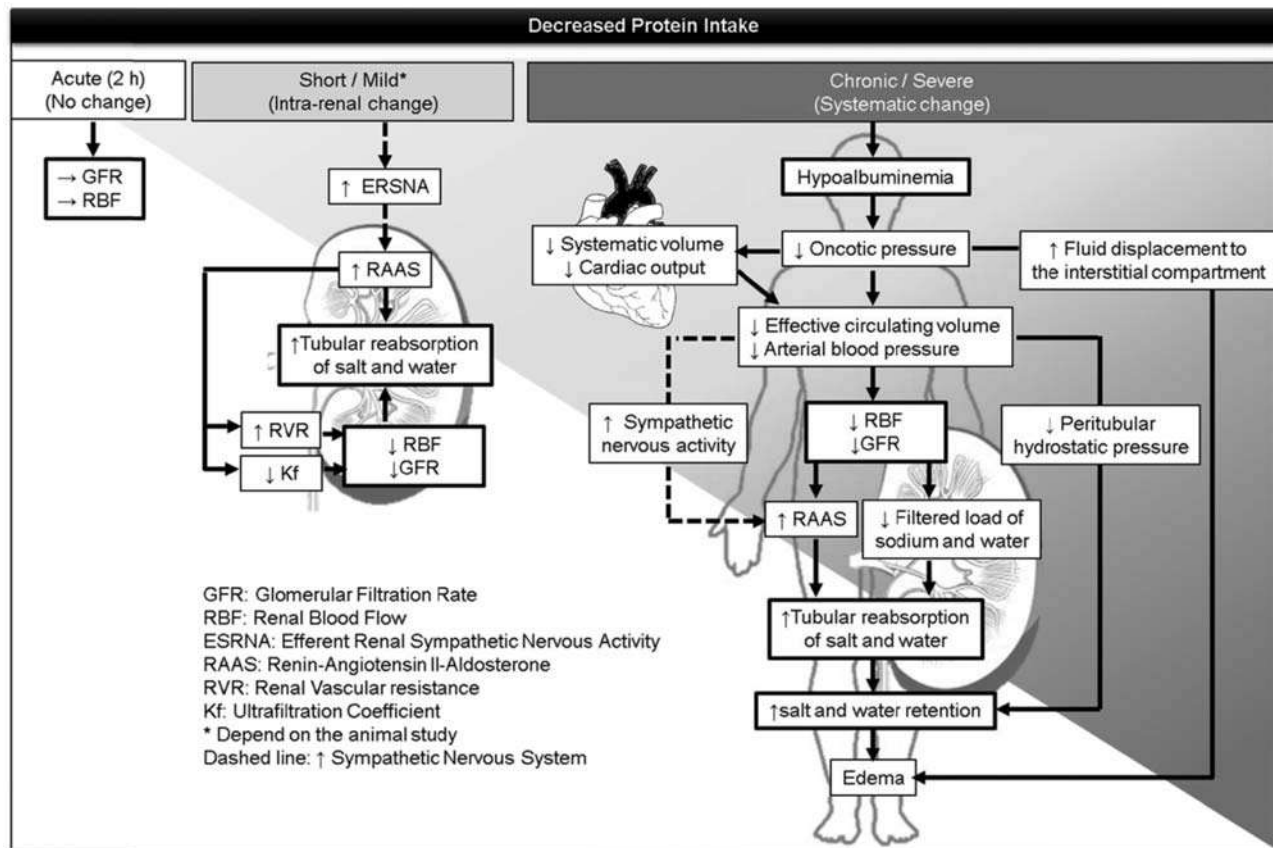

FIGURE 15.2 Impact of protein-energy wasting on glomerular filtration, renal hemodynamics, urinary concentration, and sodium excretion.

patterns of renal hemodynamic changes induced by a low-protein diet. During early stages or mild degrees of decreased dietary protein intake, systemic manifestations may be absent and reductions in renal blood flow, GFR, and tubular reabsorption of salt and water may depend on the activity of the efferent renal sympathetic nervous system, which influences renin secretion from the kidney [190,191]. With efferent renal sympathetic nerve activity stimulation, increases in angiotensin II–induced renal tubular sodium reabsorption, renal vasoconstriction, renal blood flow, and GFR are observed [191–193]. With prolonged and severe reductions in dietary protein intake, efferent renal sympathetic nerve activity and systematic changes impacting renal hemodynamics may occur. Indeed, in studies of both adults [194] and children [195] with protein-energy wasting, reductions in cardiac output have been reported. Ensuing reductions in systemic blood pressure and cardiac output may consequently lead to decreased glomerular hydrostatic pressure. However, concurrent reductions in circulating plasma protein levels would lead to decreased glomerular capillary oncotic pressure, thereby favoring glomerular filtration.

### Protein-energy wasting and laboratory measures of kidney function (serum creatinine and urea nitrogen)

Higher levels of serum creatinine and blood urea nitrogen (BUN) are used as proxies of severe kidney disease (stage 5) among patients without protein-energy wasting. However, in patients with protein-energy wasting, serum creatinine and BUN levels have a tendency to be normal or low even in the context of moderately to severely impaired GFR [181]. Reasons for the lack of rise in serum creatinine and BUN levels in this setting include (1) reductions in muscle mass ensuing from chronic deprivation of protein intake and (2) decreased protein consumption leading to reduced tissue–protein breakdown and urea reutilization (Fig. 15.3) [196]. Among adults with protein-energy wasting, habitual reductions in dietary protein intake have been associated with marked decreases in GFR ascertained by creatinine and inulin clearance [181]. However, it should be noted that patients demonstrated normal or subnormal serum creatinine and BUN levels that were normal or below normal, likely due to masking of kidney dysfunction as a result of

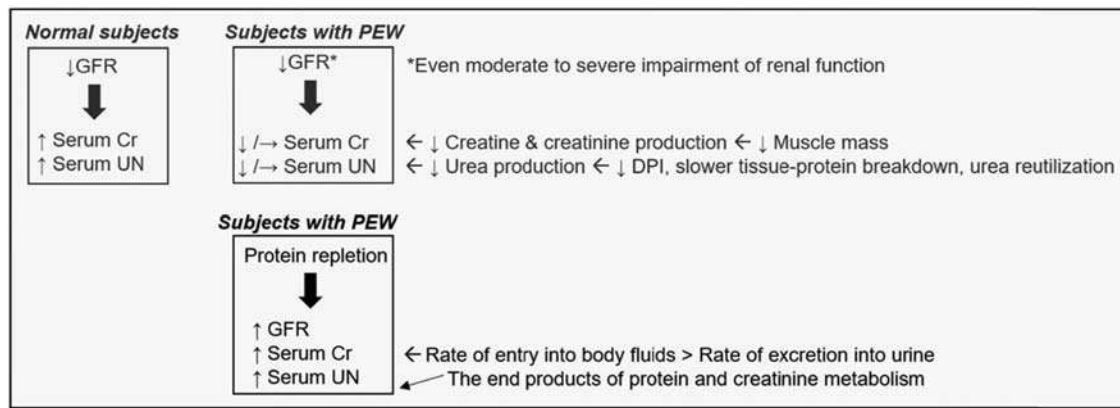

FIGURE 15.3 Impact of PEW on serum creatinine and urea nitrogen levels. In patients without PEW, GFR impairment is manifested by higher levels of serum creatinine and BUN. However, in patients with PEW, serum creatinine and BUN levels have a tendency to be normal or low even in the context of moderately to severely impaired GFR due to (1) reductions in muscle mass and (2) decreased protein intake leading to reduced tissue–protein breakdown and urea reutilization. *BUN*, Blood urea nitrogen; *Cr*, creatinine; *DPI*, dietary protein intake; *GFR*, glomerular filtration rate; *PEW*, protein-energy wasting; *UN*, urea nitrogen.

reduced muscle mass and serum creatinine and urea production.

### Protein-energy wasting and proteinuria

Several studies have examined the long-term impact of protein-energy wasting during the in utero period and in childhood upon risk of albuminuria, a marker of kidney damage and risk factor for GFR decline, cardiovascular disease, and death [197]. In a study of Dutch adults who had maternal exposure to famine at midgestation [198], there was a 3.2-fold higher risk of developing albuminuria compared to those without maternal exposure to famine, likely resulting from low birth weights and decreased nephron number. In another study of Brazilian children from the Centre for Nutritional Recovery and Education who were categorized as being well nourished, having stunted growth, being underweight, or having recovery from under-nutrition, those in the stunted growth group had an 8.4-fold higher risk of developing albuminuria [199].

### Protein-energy wasting and urinary concentration and dilution

Protein-energy wasting has also been associated with the development of polyuria and nocturia [200]; in this setting, increased urinary volumes have been observed in the context of impaired concentrating ability with preserved diluting capacity. In a study of adults with protein-energy wasting, the urinary concentrating and diluting capacities of which were examined before and after protein repletion [201], during the malnutrition phase, patients were found to have defects in urinary concentration, as shown by

diminished maximal urine osmolality and solute-free water reabsorption. In contrast, urinary dilution was found to be preserved based on normal minimal urine osmolality and free-water clearance. Notably, patients' renal responses to the administration of exogenous antidiuretic hormone (ADH) were found to be adequate, and during protein repletion, there was an improvement in urinary concentration capacity (i.e., increased maximal urine osmolality and solute-free water reabsorption) in parallel with increases in urinary nitrogen excretion.

Impaired urinary concentration in patients with protein-energy wasting is likely a sequela of decreased renal medulla osmolality resulting from low concentrations of urea in the medulla [186]. With protein repletion the urinary concentrating defect slowly resolves, presumably due to a gradual positive nitrogen balance. However, urinary urea excretion may not rise for several weeks following an increase in dietary protein intake, suggesting that a rapid restoration in the renal medullary urea gradient and osmolality is not observed. In addition, replenishment of protein mass may lead to consumption of amino acids, leaving little for urea synthesis (i.e., anabolic effect) and a subsequent blunted increase in urea excretion. In contrast, oral intake of urea has been shown to lead to a rapid increase in the urinary concentration ability after 14 hours of fluid deprivation in malnourished subjects [186], suggesting the urinary concentrating impairments observed with protein-energy wasting are due to a functional defect as opposed to an anatomic abnormality.

Additional factors that have been implicated in the development of urinary concentration defects and polyuria in protein-energy wasting include (1) inhibition of ADH secretion by the posterior pituitary

leading to decreased distal tubule reabsorption of water [200]; (2) decreased circulating amino acid levels (e.g., histidine, glutamate, and lysine) levels that enhance the hydroosmotic effect of ADH upon renal concentration capacity [202]; (3) enhanced  $\alpha_2$ -adrenergic stimulation leading to impaired ADH-induced cAMP accumulation in cortical and medullary tubules and inability to excrete maximally concentrated urine in the hyperadrenergic state of protein-energy wasting [203,204]; and (4) decreased GFR, decreased medullary thick ascending limb sodium reabsorption due to increased prostaglandin synthesis, and increased papillary plasma flow [205].

### Protein-energy wasting and acid–base disturbances

Protein-energy wasting has also been linked with acid–base disturbances. In healthy subjects, there is balanced acid production and excretion in steady state, and in the setting of an increased acid load/production from dietary intake (i.e., metabolism of dietary sulfo- and phosphor-proteins) and/or presence of organic acids, the kidney increases its excretion of acid to preserve acid–base balance. Among patients with protein-energy wasting, while normal blood pH and serum bicarbonate levels may be maintained during steady-state conditions, increased acid load/production may lead to greater severity of metabolic acidosis than observed in healthy subjects [206]. Adults [206] and children [207] with protein-energy wasting also have reduced acid excretion but typically maintain normal blood pH and serum bicarbonate levels due to decreased acid production. Indeed, the generation of hydrogen ions from metabolism, which is decreased in severe malnutrition, is typically related to protein degradation.

Research indicates that subjects with protein-energy wasting have an impaired response to acid loads [180,206]. For example, among patients with protein-energy wasting, administration of ammonium chloride ( $\text{NH}_4\text{Cl}$ ) as an acid load resulted in a marked reduction in blood pH and plasma bicarbonate levels. The net acid excretion (NAE), defined as the sum of urinary ammonia plus titratable acid minus urine bicarbonate, was markedly decreased. Upon closer examination of NAE, although the basal production of urinary ammonia was low, the intrinsic capacity of the kidney to produce ammonia in response to an acid load was impaired. In contrast with ammonia, titratable acid did not appropriately rise with an acid load. This impaired response of titratable acid excretion following an acid load may have been due to

deficiency in phosphorus, a buffer of titratable acid formation. Notably, when subjects with protein-energy wasting received a phosphorus infusion following administration of an acid load, an increase in titratable acid excretion was observed. These findings suggest that the impaired renal response to an acid load, or reduction in acid excretion, may be due to reductions in the urinary buffer, phosphorus, due to reduced dietary protein intake. Other factors contributing to impaired renal acid excretion in patients with protein-energy wasting include decreased ammonia-genesis [112], reduced gluconeogenesis [208,209], and altered transporter systems (i.e., lower proximal tubule  $\text{Na}^+/\text{H}^+$  exchange [210], decreased distal proton secretion capacity [207,211]).

### Protein-energy wasting and sodium retention

Protein-energy wasting is accompanied by impaired sodium excretion and sodium retention that may be improved with protein repletion [212]. This has been shown in a sodium-balance study of malnourished patients who were examined before and after protein repletion. While on a low-salt (10 mEq) diet, urinary sodium excretion was reduced to levels of  $\leq 10$  mEq/h. Upon consumption of a high-salt (170 mEq) diet, malnourished patients experienced a mean positive sodium balance of 400 mEq and weight gain of 2.8 kg after 5 days, whereas following protein repletion the same patients demonstrated a mean positive sodium balance of 150 mEq and weight gain of 1.2 kg on an identical diet [178].

Potential mechanisms contributing to impaired sodium excretion and sodium retention in protein-energy wasting include (1) hypoalbuminemia leading to decreased proximal sodium reabsorption due to reduced peritubular oncotic pressure; (2) impaired cardiac output leading to decreased peritubular hydrostatic pressure, decreased arterial blood pressure, and increased tubular reabsorption of salt and water; (3) decreased renal blood flow and GFR leading to reductions in the filtered load of salt and water; and (4) decreased renal blood flow and GFR leading to increased renin–angiotensin–aldosterone activity [213], thereby increasing the tubular reabsorption of salt and water [178,205].

Notably, in patients with severe protein-energy wasting who undergo dietary repletion, salt and water retention may also be observed with the development of refeeding syndrome. In this setting, insulin-mediated sodium reabsorption in the distal nephron may occur as a consequence of increased circulating insulin levels in the early phases of refeeding [214–216].

## Effects of maternal nutrition on renal development

Maternal and paternal nutritional statuses have an important bearing on organ development and function, including that of the kidneys. Experimental animal models and epidemiologic data have shown that maternal malnutrition and/or low infant birth weights are linked with subsequent development of cardiovascular disease, hypertension, obesity, type 2 diabetes, the metabolic syndrome [217], as well as CKD and ESRD in later life [218].

## Protein-energy wasting and renal development

Growing evidence has supported an association between exposure to maternal malnutrition and development of kidney disease. For example, findings from the Dutch Famine Study have shown that maternal exposure to extreme famine in midgestation is associated with increased risk of microalbuminuria in their adult offspring, presumably due to decreased formation of glomeruli [219]. In another natural experiment the impact of maternal exposure to the Chinese famine during gestation as well as in early postnatal life (i.e., first 2 years of life) was associated with higher risk of proteinuria in adulthood [220]. In contrast to the Dutch study that examined a previously well-nourished population upon whom famine was imposed, the Chinese study examined adults who had chronic malnutrition prior to famine exposure. However, the aforementioned studies should be interpreted with caution due to their methodologic limitations, including inadequate adjustment for key confounders (i.e., maternal health status, smoking status, weight) and unclear accuracy of reported maternal nutritional status [221].

## Isocaloric protein restriction and renal development

Animal models of maternal isocaloric protein restriction (i.e., dietary protein intake accounting for 5%–12% of total energy intake) versus controls (i.e., dietary protein intake accounting for 18%–20% of total energy intake) during gestation have been consistently associated with lower birth weight, decreased nephron number, increased blood pressure, and kidney dysfunction in offspring [222–228]. To date, one human study has investigated the relationship between maternal protein intake and offspring kidney health [229]. In this study, higher maternal total and vegetable protein intake, but not maternal animal protein intake, during the first trimester of pregnancy were associated with higher eGFRs in childhood. However, first-trimester

maternal protein intake was not significantly associated with childhood kidney volume, cystatin C–based eGFR, nor the risk of microalbuminuria. Protein restriction prior to conception [230] has also been shown to have long-term effects on kidney development. An experimental study of rats that underwent isocaloric protein restriction prior to conception followed by a control diet from onset of pregnancy demonstrated decreased kidney growth and lower relative kidney weights at 180 days [230]. In summary, early nutritional exposures in the pre- and peri-conception period and over the course of pregnancy have an important bearing on kidney growth and/or function in later life.

## Conclusion

In summary, dietary macronutrients are key modulators of kidney health outcomes. While a large body of data demonstrate the major role of dietary protein intake on renal hemodynamics, kidney function, and renal morphology, further investigations are warranted to advance our understanding of the effects of other macronutrients (e.g., carbohydrate, fat) and dietary patterns upon kidney health and longevity. In addition, while a number of studies have shown the acute renal physiologic changes observed with protein-energy wasting, further research is needed to determine the long-term sequelae of sustained deprivation of macronutrients on renal outcomes.

# Dietary interventions to slow the progression of chronic kidney disease and improve metabolic control of uremia

*Denis Fouque*

Department of Nephrology, Nutrition and Dialysis, Hospital Lyon-Sud, Hospices Civils de Lyon and University Claude Bernard Lyon1, Lyon, France

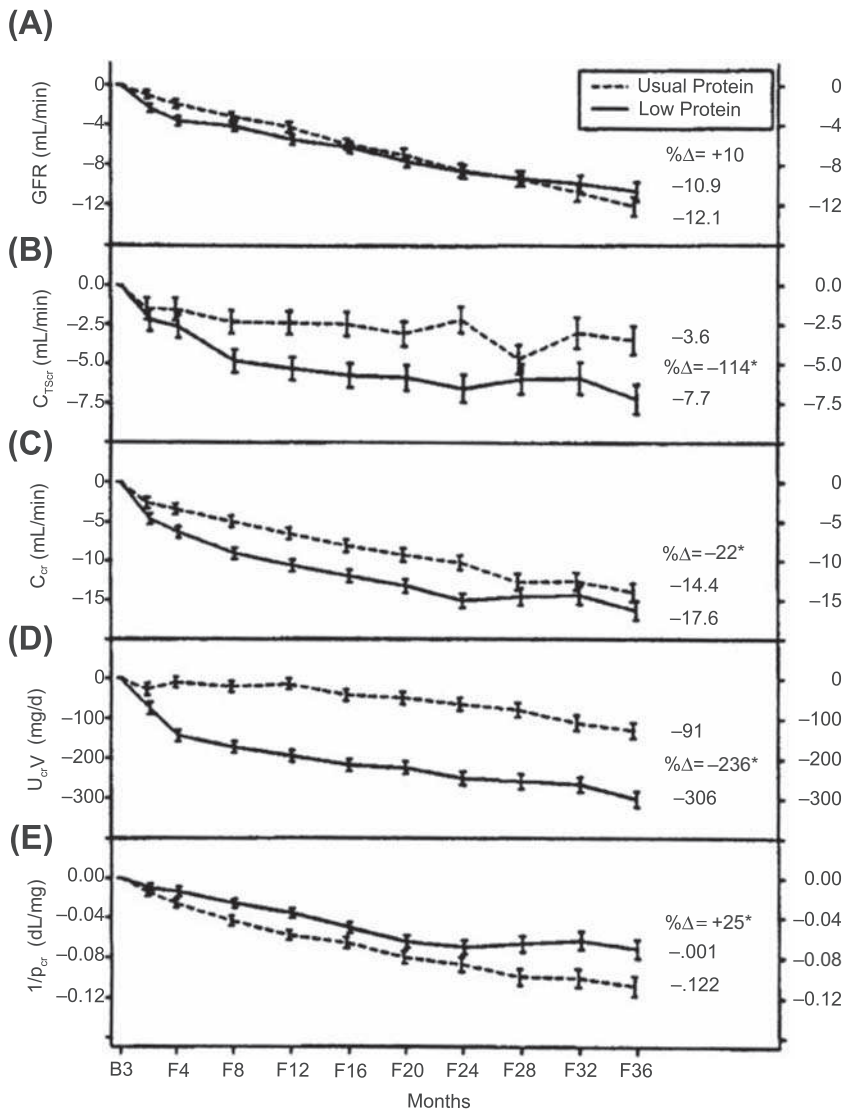

For many decades, it has been recommended that patients with kidney disease should modify their nutrient intakes. Depending on the disease, these advices are generally focused on salt, protein, potassium, calcium, phosphorus, alkaline derivatives, oxalates, citrates, products that engender uric acid, and obviously water or fluid intake. In this chapter, we will focus on the experimental and clinical effects of protein intake on kidney function in patients with a chronic reduction in glomerular filtration rate (GFR) who do not have end-stage kidney disease. We will address the potential benefits and risks of limiting the patient's protein intake to an optimal level, and how to monitor the actual intake of these diets. In addition, the clinical evidence that justifies such dietary interventions in patients with chronic kidney disease (CKD) will be discussed.

## Assessing the progression of chronic kidney disease

One of the main questions that arise when investigators want to study nephroprotection is how the progression of kidney disease should be monitored. Experimental studies frequently present histological data such as glomerular sclerosis, tubular atrophy, and interstitial fibrosis in response to diet interventions. However, such data are not available in humans, since ethical reasons prevent the performance of serial kidney biopsies during dietary interventions. Since kidney failure is the ultimate consequence of progressive kidney disease, kidney function and its impairment is usually considered a key outcome measure in experimental as well as clinical trials. However, one of

the main limitations of this approach is that renal function is directly affected by nutritional intake independently of injury to kidney tissue. Thus interpretation of traditional markers of renal function could be flawed by nutritional interventions. To illustrate this point, Levey et al. have summarized the renal function decrease during the Modification of Diet in Renal Disease (MDRD) study using different estimates of GFR, in both groups of usual and low-protein intake diets (Fig. 16.1). If we accept the <sup>125</sup>I-iothalamate renal clearance as the gold standard for GFR measurement, it is easy to note that other traditional renal function markers are not as accurate measures of GFR and can lead to misinterpretation. Although it is not the aim of this chapter to present detailed information on how to monitor renal function in experimental and clinical studies, some brief comments related to nutritional influences may be warranted.

Serum creatinine has been extensively used to monitor renal function and to assess kidney disease in clinical trials [1]. It is now well established that serum creatinine or its derivatives are not accurate indicators of renal function [2]. Serum creatinine is produced by the muscle catabolism of creatine, 1.7% of the entire muscle creatine pool is converted to creatinine daily. This conversion rate does not appear to be extremely constant, since the daily variability in this conversion rate, in healthy volunteers, has been reported to range from 6% to 26% [3]. Serum creatinine is also affected by creatine and creatinine intake from cooked meat [4]. Indeed, those investigators reported that serum creatinine increased by as much as 50% from normal values within 2–4 hours after a meal containing 225 g of boiled beef [4]. The halftime to achieve

Effects of diet and antihypertensive therapy on creatinine clearance and serum creatinine concentration in the Modification of Diet in Renal Disease Study. *J Am Soc Nephrol* 1996;7(4):556-66.

a new steady state in creatinine excretion following a change in creatine intake is 41 days [5]. Thus any change in creatine intake (e.g., in intake of animal skeletal muscle) will necessitate a minimum of three half-lives to reach a new plateau, for example, 4 months after the start of the new diet, and before any valid estimation of renal function from creatinine could be done. In addition, any change in the diet that leads to a variation of muscle mass will modify the creatine pool and creatinine production [6]. For instance, intensive physical exercise leading to hypertrophy of skeletal muscle will induce a rise in serum creatinine independent of renal function change.

Serum creatinine may also vary independently of renal function and food intake for additional reasons. First, there is intervariability between measurement techniques among different clinical laboratories that can exceed 30–40  $\mu\text{mol/L}$  for the same sample. Second, the level of serum creatinine depends on the tubular secretion of creatinine, which has a great variability,

particularly in the range of 40–80 mL/min of GFR [7]. In addition, the tubular secretion of creatinine is impaired by many medications such as trimethoprim, cimetidine, salicylate, or probenecid. These drugs will generally block the tubular secretion of creatinine, increasing serum creatinine without a change in GFR. Creatinine is also metabolized by extrarenal routes, mostly degraded by intestinal microorganisms, and this extrarenal clearance may vary as kidney disease progresses [8].

Since it has been showed that in most kidney diseases, there is a linear loss of renal function over time in more than 80% of patients, the inverse of serum creatinine ( $1/\text{Secret}$ ), which also decreases linearly with time, has been used as a surrogate for estimating kidney function. Unfortunately, all of the limitations that exist using the serum creatinine as an indication of GFR also pertain to the reciprocal of the serum creatinine, thus rendering this marker unsuitable for assessing diet impact on renal function.

Creatinine clearance, serially measured, has been proposed as an indicator of kidney function loss. Creatinine clearance is not an ideal method for assessing glomerular filtration, since it exceeds the GFR by 10–15 mL/min (in healthy adults) due to active tubular secretion. As kidney function deteriorates further, the tubular secretion increases disproportionately and can overestimate kidney function by 80%–100% in cases of severe kidney insufficiency [7,9]. The correlation between the creatinine clearance and true GFR is weak and improves after administering cimetidine (800 or 1200 mg), which blocks the tubular part of creatinine clearance, 1–2 hours before commencing the urine collection [9–11]. In the pilot phase of the MDRD study, the mean correlation between the rate of change in creatinine clearance (24-hour urine collection) and GFR (125I-iothalamate clearance) was only 0.56 and 0.50 in Studies A and B, respectively [12]. Another important nonspecific cause of inaccurate estimation of kidney function by the creatinine clearance is an incomplete urine collection. This inaccuracy tends to improve when short-period repeated urine collections are done over a 3- to 4-hour period [10,13]. Thus

MDRD study and proposed a formula based on serum creatinine, serum urea, serum albumin, age, gender, and ethnicity, which is more accurate than creatinine clearance or the Cockcroft–Gault equation (Eq. 16.2) [17].

$$CCr = [(140 - \text{age}) \times \text{Weight}] / (P_{\text{creat}} \times 72) \quad \text{for men} \quad (16.1)$$

$$CCr = [(140 - \text{age}) \times \text{Weight}] / (P_{\text{creat}} \times 85) \quad \text{for women}$$

where CCr is creatinine clearance in mL/min,  $P_{\text{creat}}$  is serum creatinine in mg/dL, age in years, and weight in kg (from Ref. [14]).

$$GFR = 170 \times [P_{\text{creat}}] - 0.999 \times [\text{Age}] - 0.176 \times [0.762 \text{ if patient is female}] \\ \times [1.180 \text{ if patient is black}] \times [\text{SUN}] - 0.170 \times [\text{Alb}] + 0.318 \quad (16.2)$$

where GFR is the GFR in mL/min/1.73 m<sup>2</sup>,  $P_{\text{creat}}$  is serum creatinine in mg/dL, Age in years, SUN is serum urea nitrogen in mg/dL, and Alb is serum albumin in g/dL (from Ref. [17]).

More recently, Levey et al. identified a new formula [18] called CKD-EPI (Chronic Kidney Disease - Epidemiology Collaboration), using different thresholds based on race, gender, and serum creatinine:

<b>Black</b>	
Female	≤62 (≤0.7) >62 (>0.7)
Male	≤80 (≤0.9) >80 (>0.9)
<b>White or other</b>	
Female	≤62 (≤0.7) >62 (>0.7)
Male	≤80 (≤0.9) >80 (>0.9)

$$GFR = 166 \times (\text{Scr}/0.7)^{-0.329} \times (0.993)^{\text{Age}}$$

$$GFR = 166 \times (\text{Scr}/0.7)^{-1.209} \times (0.993)^{\text{Age}}$$

$$GFR = 163 \times (\text{Scr}/0.9)^{-0.411} \times (0.993)^{\text{Age}}$$

$$GFR = 163 \times (\text{Scr}/0.9)^{-1.209} \times (0.993)^{\text{Age}}$$

$$GFR = 144 \times (\text{Scr}/0.7)^{-0.329} \times (0.993)^{\text{Age}}$$

$$GFR = 144 \times (\text{Scr}/0.7)^{-1.209} \times (0.993)^{\text{Age}}$$

$$GFR = 141 \times (\text{Scr}/0.9)^{-0.411} \times (0.993)^{\text{Age}}$$

$$GFR = 141 \times (\text{Scr}/0.9)^{-1.209} \times (0.993)^{\text{Age}}$$

(16.3)

to assess the effects of a given intervention on kidney function in a clinical trial, creatinine clearance can be used under the following conditions: the range of kidney function of patients should be wide, the treatment does not affect the tubular secretion of creatinine, and the clearance is measured during short periods [10,13]. Whether “cimetidine” creatinine clearance should be performed in diet intervention studies has not yet been validated but perhaps should be considered when true GFR measurements cannot be employed.

Recently, a number of formulas have been derived from creatinine and various parameters such as age, gender, and weight (Eq. 16.1) [14–16]. These formulas appear convenient to use, can be computed directly from simple software or pocket organizers, and have broad applicability for the general treatment of kidney disease. Levey and colleagues reanalyzed the data obtained through the

However, although simple formulas can predict GFR with acceptable precision for routine use (Cockcroft–Gault formula overestimates GFR by only 16%, e.g., 7 mL/min/1.73 m<sup>2</sup>, [17]), for research purposes, more precise techniques should be used.

GFR is considered to be the gold standard for estimating renal function and for assessing the progression of kidney disease [2]. However, the GFR measurement is difficult to perform, expensive, and also presents some limitations. Traditional markers such as inulin have been challenged by radiotracers such as 125I-iothalamate, 99mTc-DTPA, or 51Cr-EDTA. Measurements can be done after a single injection, either subcutaneously or intravenously, and include plasma and/or urine samples over 3–4 hours. Usually, when urine samples are needed, bladder catheterization is not necessary but may be required in cases of bladder dysfunction such as in

diabetes or neurological disease. To avoid prerenal azotemia, it is generally recommended to ensure a minimal urine output by ingesting a water load before the test. Anastasio and colleagues have challenged this fact while actually reporting a decrease in GFR after patients received a large oral water load (4 mL/kg body weight every 30 min) during a 3-hour GFR measurement [19].

Finally, another more pragmatic approach has been proposed recently to assess the efficacy of a treatment in kidney failure. The “renal death” was defined as the number of patients starting dialysis during a study [1]. Since it cannot formally be excluded that the death of a patient is not from kidney failure origin, we have included the number of death within the “renal death” definition, as well as the number of kidney transplantation before the start of dialysis if it happened during the study.

### Protein intake and chronic kidney disease: Experimental data

There is ample evidence, dating from the 1920s, that elevated protein intake or amino acid infusion alters kidney hemodynamics and impairs renal function and tissue in normal animals or experimental kidney insufficiency [20–25] (for detailed reviews see [26–28]). In many of these experiments, it is somewhat difficult to clearly identify the specific role of protein per se, since sodium, energy, fluid, and phosphorus intakes obviously varied and were not always controlled. In addition, in the case of severe experimental nephropathy, high-protein intake may have elicited superimposed uremic toxicity and mortality not directly related to kidney function or kidney damage, thus adding confounding elements [21]. We will review here the experimental data on the renal effects of a reduced protein intake.

### Effects on renal hemodynamics

The hemodynamic effects of dietary protein have been attributed to a number of mechanisms that eventually increase GFR, induce and/or increase proteinuria, and lead to glomerulosclerosis and kidney failure. Candidates for these mechanisms include hormones [glucagon, insulin, insulin-like growth factor-1 (IGF-1), and angiotensin II (AII)], cytokines (prostaglandins), and kinins [29–33]. Intrarenal regulation of sodium transport may also be involved through the proximal sodium/amino acid cotransporter; activity of this transporter is enhanced in response to an increased filtered amino acid load, thus stimulating the tubuloglomerular feedback and increasing the GFR [34]. Protein restriction ablates most of the hemodynamic changes observed after kidney ablation or 5/6 nephrectomy. Micropuncture studies provide direct

evidence that the increase in single-nephron GFR after kidney mass reduction is responsible for the accelerated glomerular injury [35]. Reducing protein intake decreases GFR in normal animals and blunts the renal hemodynamic changes induced by extensive kidney ablation, that is, increased glomerular pressure and flow. Subsequent studies in rats with less severe kidney ablation showed that a low-protein intake also lowers hyperfiltration and retards the onset of proteinuria and glomerular fibrosis [23,36,37]. In addition to these experimental data, low-protein intakes also increased survival in these animals with reduced kidney function [21].

A reduced animal protein intake (usually a diet containing 6% protein) allows the control of glomerular hypertension by inducing afferent arteriolar vasoconstriction, which, in turn, decreases the glomerular plasma flow and reduces proteinuria [35]. Protein restriction decreases the percentage of glomerular sclerosis and proteinuria. Indeed, Hostetter and colleagues reported that at 4 and 8 months after the onset of kidney disease created by a 5/6 nephrectomy, glomerulosclerosis was attenuated by 50% in animals receiving a 6% protein diet and proteinuria was lowered to 25% of that in rats receiving a 40% protein diet [23]. Of importance, these benefits were observed at different levels of kidney disease (Fig. 16.2).

Micropuncture studies in 5/6 nephrectomized rats showed that a reduction in protein intake from 20% to

FIGURE 16.2 Percentage of sclerosed glomeruli in two different levels of experimental renal insufficiency as compared with a control group of rats. Open circles: low protein intake; close circles: high protein intake. Source: From Hostetter TH, Meyer TW, Rennke HG, Brenner BM. Chronic effects of dietary protein in the rat with intact and reduced renal mass. *Kidney Int* 1986;30(4):509–517.

6% led to a reduction in single-nephron GFR and intra-glomerular capillary pressure to normal [25]. Of interest, proteinuria in the 6% protein diet group was reduced to one-fifth of proteinuria observed in the 20% protein diet group. Both groups of rats were hypertensive, and there was no discussion on what the effects of a low-protein diet would have been if the rats were normotensive [25]. Thus whereas a low-dietary protein intake shortly commenced after the onset of kidney ablation seems to mainly blunt the increase in glomerular capillary pressure, a delayed low-protein diet will reduce glomerular capillary pressure without lowering kidney hyperperfusion or hyperfiltration [25,38]. These data support the deleterious impact of glomerular hypertension, and the protective role of a low-protein intake on the remnant renal function in experimental kidney disease.

### Effects on oxidant stress and inflammation

Protein intake and protein trafficking through the kidney are associated with hypermetabolism [39] and oxidant stress [40]. Oxygen consumption and ammonia production decreased by about 50% when rats were fed with a 12% instead of a 40% protein diet [40]. This fact is primarily explained by a decrease in net sodium reabsorption [41]. In another study, hypoxic injury of the thick ascending limb was mitigated by reducing the protein content of the diet [42]. Additional metabolic data obtained through <sup>31</sup>P-NMR spectroscopy also show that protein restriction reduces intracellular inorganic phosphate and pH, consistent with a decrease in oxygen consumption [43]. This decrease in oxygen demand secondary to a reduction in protein diet from 30% to 6% may be responsible for reduced kidney production of glutathione and malondialdehyde [41,43].

Other studies have addressed the potential kidney antifibrotic effect of a low-protein diet. Nakayama and colleagues reported that in adriamycin-treated rats, expression of fibronectin and TGF- $\beta$  in the kidney was dramatically reduced when animals received a 6% protein diet as compared with their littermates receiving a regular 20% protein diet [44]. In addition, these investigators showed a posttranscriptional reduction in fibronectin synthesis after short-term (2-week) treatment with a low-protein diet, whereas there was no difference in fibronectin gene expression. These interesting observations bear similarities to the effects of energy and protein intakes on the transcriptional and posttranscriptional regulation of IGF-1 synthesis in liver cells [45,46].

TGF- $\beta$ , a potent profibrotic agent, is decreased by intervention with low-protein diets. Peters and colleagues documented two sets of findings in this regard: first, L-arginine supplement augmented the propensity

of a low-protein diet (6%) to reduce the glomerular expression of TGF- $\beta$ , fibronectin, and plasmin activator inhibitor 1 (PAI-1) in a model of immune glomerulonephritis [47], independent of nitric oxide metabolism. Second, whereas maximal AII blockade by very high doses of either ACEI (angiotensin converting enzyme inhibitor) or AII antagonists resulted in only a 45% decrease in TGF- $\beta$  gene expression and protein production, the addition of a low-protein diet to other well-established nephroprotective treatments resulted in a further 20% reduction in TGF- $\beta$  expression and production, and this was associated with a similar decrease in fibronectin and PAI-1 [48]. It should be emphasized that in both experiments the control of profibrotic mediators was associated with a concomitant decrease in proteinuria. These findings provide good evidence that a low-protein diet possesses its own therapeutic actions, independent from ACEI or AII antagonists on kidney scarring.

Tovar-Palacio and colleagues [49] studied the effects on kidney tissue of different amounts and nature of protein intake in obese Zucker rats. These animals that had normal renal function ingested either casein or soy protein, in an amount of 20%, 30%, or 45% of the food intake for 2 months. Urine excretion of hydrogen peroxide, a marker of oxidative stress, increased in a parallel manner to the protein intake, and for the same amount of protein in the diet, was consistently lower in the vegetal source of protein as compared with the animal one. Proteinuria followed the same trend and was lowest in the 20% soy protein diet [49]. Furthermore, kidney expression of genes involved in inflammation (IL-6 and TNF- $\alpha$ ), lipid metabolism (SREBP-1 and FAS), matrix accumulation (type IV collagen), and fibrosis (TGF- $\beta$ ) was lowest in the 20% soy diet and highest in the 45% casein diet. Although these rats did not have kidney failure, these results strongly support a deleterious effect of high casein intake and a nephroprotective impact on low protein from vegetal source [49].

Studies have addressed the potential role of endothelin (ET) as a cause of puromycin-induced glomerulosclerosis. In addition, ET-1 gene expression has been reported to be elevated in other kidney mass reduction experiments. Nakamura et al. reported that a 6% protein diet was able to reverse proteinuria and increase ET receptor mRNA, ET-1 mRNA, and protein in puromycin-induced glomerulosclerosis as compared with rats receiving a 22% protein diet [50]. Whether this improvement occurs through a reduction in factors that stimulate ET release, for example, TGF- $\beta$  and TNF- $\alpha$ , has not been directly proven in this experiment but represents a possibility [51].

Kruppel-like factor-15 (KLF-15) is a transcription factor that has been showed to reduce cardiac fibrosis. Gao et al. [52] studied KLF-15 in 5/6 nephrectomized rats

receiving either a controlled (22%), or low-protein intakes (6% or 5% + 1% ketoacids) for 6 months. As expected, proteinuria, glomerular sclerosis, and tubular fibrosis were reduced in both LPD (low protein diet) and LPD + KA (ketoanalogues) groups, but to a greater extent in the LPD + KA rats [52]. Kidney expression of profibrotic factors (TGF- $\beta$ , fibronectin, and type IV collagen) was dramatically reduced in both LPD groups, as were proinflammatory markers (TNF- $\alpha$ , MCP-1, and RANTES). As a consequence of increased TGF- $\beta$  and TNF- $\alpha$  production in CKD rats receiving the control protein, KLF-15 expression was completely abolished, whereas LPD or LPD + KA almost restored KLF-15 expression to normal. For virtually all measurements, LPD + KA did improve KLF-15 better than LPD alone [52]. Thus there is an extensive data set to support the kidney antioxidant, antiinflammatory, and antifibrotic effect of a reduction in protein intake in experimental kidney disease.

### Effects of the source of dietary proteins

As already shown earlier by Tovar-Palacio et al. [49], the effect of the type of protein deserves further comments. Based on the observation that vegetarians have lower GFR than omnivores [53,54], Williams et al. tested two different sources of protein derived from either animal or vegetable origin, casein, or soya, in stable CKD rats [55]. Both regular (24%) and moderately low (12%) protein intakes of each of those two protein sources were studied. After 3 months of dietary feeding, glomerulosclerosis and tubular dilation were found to be always greater in the casein- versus soya-fed groups. Proteinuria was greatest with the 24% [ $99 \pm 34$ (sd) mg/day] and 12% ( $64 \pm 18$ ) casein diet, lower in the 24% soya group ( $30 \pm 5$ ), and lowest in the 12% ( $35 \pm 7$ ) soya groups. There was no difference in the severity of the proteinuria or histological lesions in the 24% versus the 12% soya groups [55]. Although these results are convincing, it should be noted that, due to the different digestibility of protein, it is possible that vegetable proteins were less absorbed than the animal proteins by about 10%, thus reducing the true protein load with the former diet. It is interesting to note that particular amino acids may elicit specific renal hemodynamic effects. A diet enriched with L-arginine, the precursor of nitric oxide (NO), has been shown to reduce glomerular hypertension and glomerulosclerosis in 5/6 nephrectomized rats [56]. Because NO is a potent vasodilation factor, locally enhanced NO production may be involved in these hemodynamic changes. L-Arginine also stimulates growth hormone secretion, which may also cause renal vasodilation through the release of IGF-1, and consequently, NO.

### Protein and/or energy intake?

Venkatachalam and colleagues developed another interesting hypothesis. Since in most studies of protein reduction, it is the whole food intake that is reduced, these authors have studied the effects of energy restriction as compared with protein restriction [57]. Five groups of 5/6 nephrectomized rats were fed either a control diet, a 40% reduction in overall food, a 40% energy-reduced diet, a 40% protein-reduced diet, and a 40% salt-reduced diet. After 21 weeks of diet, histological findings clearly showed protected kidneys in the low energy alone group, which disclosed less glomerulosclerosis as well as less interstitial inflammation, as compared with all other groups. Of interest, proteinuria was lowest in this calorie-restricted group [57]. The discrepant finding of an absence of beneficial effects of the protein-reduced diet might be explained by a too modest reduction in protein intake as compared to the control diet. In a subsequent paper, these investigators reported that 2 weeks after 5/6 nephrectomy, the kidney IGF-1 content and the severity of inflammatory lesions were reduced with calorie restriction [58]. Altogether, these results suggest that IGF-1 expression could be involved in the tubulointerstitial inflammatory response and controlled by a low energy intake. Of interest is the fact that proteinuria was also reduced by the low-calorie diet [58].

In a strain of mice (kD/kD) developing an autoimmune interstitial nephritis, Fernandes et al. showed that a low-protein diet alone did not reduce mice mortality as compared with a combined protein and calorie restriction which induced the largest survival in animals [59]. However, the suppression of immune disease may be a more important cause of reduced mortality than any alteration in kidney metabolism or physiology in this experiment. Since in patients, reducing energy intake to a level that may induce malnutrition is not considered appropriate or justifiable, the relevance of these energy intake-reducing studies to clinical medical care may be quite limited.

It should be emphasized that the effects of a low-protein diet in reducing proteinuria may impact on tubular atrophy and apoptosis [60]. Indeed, there is a toxic role of serum albumin on tubular cells in culture [61,62]. Two sets of experiments have highlighted the role of protein delivery to the tubule in increasing interstitial fibrosis [63] and tubule cell apoptosis [64]. Indeed, the dramatic increase in proteinuria following intraperitoneal bovine serum albumin is associated with a profound tubular apoptotic reaction. Thus since most experiments have shown that reducing protein intake is associated with a reduction in proteinuria [65], it is possible but not proven that a low-protein intake also reduces kidney apoptosis.

In summary, there is a whole set of evidence from experimental research that high-protein loads are hazardous to the kidney, and that a large number of the physiopathological changes that occur secondary to reduced functioning kidney mass or kidney disease are corrected or, at most, improved by diets low in protein. However, these experiments use the extreme ends of dietary protein content, to identify these histological and hemodynamic changes. For example, Neugarten et al. reported that the kidney injury and proteinuria of puromycin-treated rats improved with a diet providing 4% protein, as compared with a group of rats receiving a 50% protein diet [66]. How do these extremely different protein diets compare with clinical studies? How would humans respond to low-protein diets? What is the evidence for the nutritional safety of low-protein diets? Could it be possible to adhere to such diets for long periods of time? How to monitor compliance? These questions will now be addressed.

## Dietary protein intake: Clinical studies

### Protein requirements in normal individuals

In the United States the daily average protein intake is about 90–110 g in adult men and 65–70 g in adult women, and 1.3 g/kg in most European countries. Protein intake tends to diminish by 15% by the age of 70 [67]. In women the mean protein intake is 30%–50% lower than in men for the same age [68] and is in accord with their 40% lower muscle mass as compared with men [69]. Thus based on the FAO recommendations, most adults in occidental countries have protein intakes far above the recommended allowance, which currently is 0.75 g/kg/day [70]. Furthermore, it should be emphasized that the 0.75 g/kg body weight value is defined as the safety level, including two standard deviations above the average requirement obtained through individual metabolic balances, thus guarantying that at least 97.5% of subjects will attain neutral or positive nitrogen balance [70]. Fortunately, due to the Gaussian distribution of protein requirements, many normal individuals will be in neutral protein balance with a lower level of protein intake. This fact may partly explain why in maintenance dialysis, patients, some individuals, present with nPNA (normalized protein nitrogen appearance) lower than recommended and show little or no signs of protein malnutrition.

In patients with CKD, from the perspective of the nutritional needs to maintain healthy body composition, there is no need to increase or decrease these recommended dietary protein levels. Indeed, in stable adult patients, most nitrogen balance and protein turnover studies have confirmed these data (see later). In addition, it should be noted that during the progression of kidney

disease, spontaneous alterations in nutrient intake frequently occur, generally in the form of a reduction in both energy and protein intake [71–73]. Indeed, in an NHANES survey, it was reported that in patients with an estimated GFR between 30 and 60 mL/min, spontaneous energy and protein intakes were  $23.3 \pm 0.7$  (sem) kcal/kg/day and  $0.91 \pm 0.03$  g protein/kg/day, and in patients with a GFR less than 30 mL/min the values were  $20.9 \pm 1.0$  kcal/kg/day and  $0.86 \pm 0.03$  g protein/kg/day [74]. These findings are of particular clinical importance, because when there is a deficient energy intake, the body cannot adjust as readily to a reduction in protein intake. Thus in the absence of a dietary control and care plan, patients with CKD will nutritionally do worse than if they were enrolled in an optimal low protein and adequate energy intake diet [73,74].

In addition to this information, high-protein intakes have been shown to impair kidney function. Two large recent studies and one review have highlighted the deleterious effect of high-protein intakes on the progression of kidney damage [75–77]. Finally, the NephroTest study, another large-scale French prospective cohort of stage 3 CKD patients followed for up to 3 years, showed a linear positive association between protein intake (assessed independently by both urinary nitrogen output and dietary intake) and the need to start maintenance dialysis. Patients eating 1.2 g protein/kg/day had a 30% increase in dialysis need compared with patients with a protein intake of 0.6 g/day [78]. It should be noted that these patients were in a daily life cohort without any dietary advice or restriction.

### Metabolic effects of low-protein diets in human

#### *Metabolic adaptation to a reduction in protein intake*

Fig. 16.3 shows the metabolic adaptation that occurs when an ad libitum protein diet (1.1 g/kg/day) is changed to a more limited protein intake (0.7 g/kg/day) in 12 patients with moderate CKD without the nephrotic syndrome [79]. Using a whole-body amino acid tracer (i.e.,  $^{13}\text{C}$ -leucine), the investigators reported a net decrease in leucine oxidation, which is considered to reflect the excess amino acid catabolism; these findings suggest a normal adaptation in protein metabolism, similar to that reported in healthy volunteers [80]. There was no change in patients' body weight, serum albumin, or IGF-1 after the 3 months of this reduced protein intake, confirming the safety of this level of protein intake (0.7 g/kg/day) in CKD [79]. Other studies have reported similar findings in CKD patients undergoing different types of diet intervention but mostly with shorter studies. Goodship et al. studied six patients with moderate CKD during a short-term (1 week)

FIGURE 16.3 Total body leucine oxidation, a marker of protein metabolism, before and after ingestion of a low-protein diet for three months in 12 patients with moderate CKD (1.1g prot/kg/day in baseline vs 0.7 g/kg/day in LPD). The data demonstrate an adequate adaptation to a reduced protein intake (\* $p < 0.05$  from baseline). Source: From Bernhard J, Beaufre B, Laville M, Fouque D. Adaptive response to a low-protein diet in predialysis chronic renal failure patients. *J Am Soc Nephrol* 2001;12(6):1249–1254.

regular (1 g protein/kg/day) or reduced (0.6 g protein/kg/day) protein intake and with energy intakes of 32.5 kcal/kg/day [81]. Fasting leucine oxidation did not significantly change with the low-protein intake, whereas postprandial leucine oxidation decreased by about 25% ( $P < .05$ ). As in nephrotic patients without chronic kidney failure [82], these data show that patients with mild kidney insufficiency can adapt their protein metabolism during acute or chronic reductions in protein intake by reducing amino acid oxidation during both the postprandial and the fasting state.

More restricted protein intakes have been shown to reduce amino acid oxidation by a greater magnitude. Masud et al. reported in six severe nondialysis CKD patients that a diet providing 0.35 g protein/kg/day supplemented with either ketoacids or essential amino acids for 25 days maintained neutral nitrogen balance and body composition [83]. These diets were associated with very low leucine oxidation rates that were not different whether patients were supplemented with ketoanalogues or essential amino acids [83]. In a long-term follow-up of these patients (16 months), the fasting leucine oxidation rate remained at the low level of  $10.0 \pm 2.2 \mu\text{mol/kg/h}$  [84]. In response to a lower protein intake, these values for amino acid oxidation appear to be more reduced than was observed in studies with less restricted protein intakes [79,81], suggesting a potential “functional reserve” for protein sparing in CKD patients.

Maroni and colleagues studied patients presenting with heavy proteinuria, for example,

greater than 6 g/day, and moderate CKD (GFR, about 50 mL/min/1.73 m<sup>2</sup>). Using leucine turnover and nitrogen balance techniques, they showed that a reduction from 1.85 to 1.00 g protein/kg/day in the patients induced adaptive protein conserving mechanisms that were similar to these of healthy volunteers and that the patients sustained positive nitrogen balance [85]. These results have been confirmed by Giordano et al. in seven patients with heavy proteinuria [82]; with a reduction in protein intake from 1.20 to 0.66 g/kg/day for 1 month, endogenous leucine flux decreased by 8% ( $P < .05$ ), hepatic albumin synthesis decreased from 18.2 to 14.9 g/1.73 m<sup>2</sup> ( $P < .03$ ) and serum albumin rose from 2.88 to 3.06 g/dL ( $P < .03$ ).

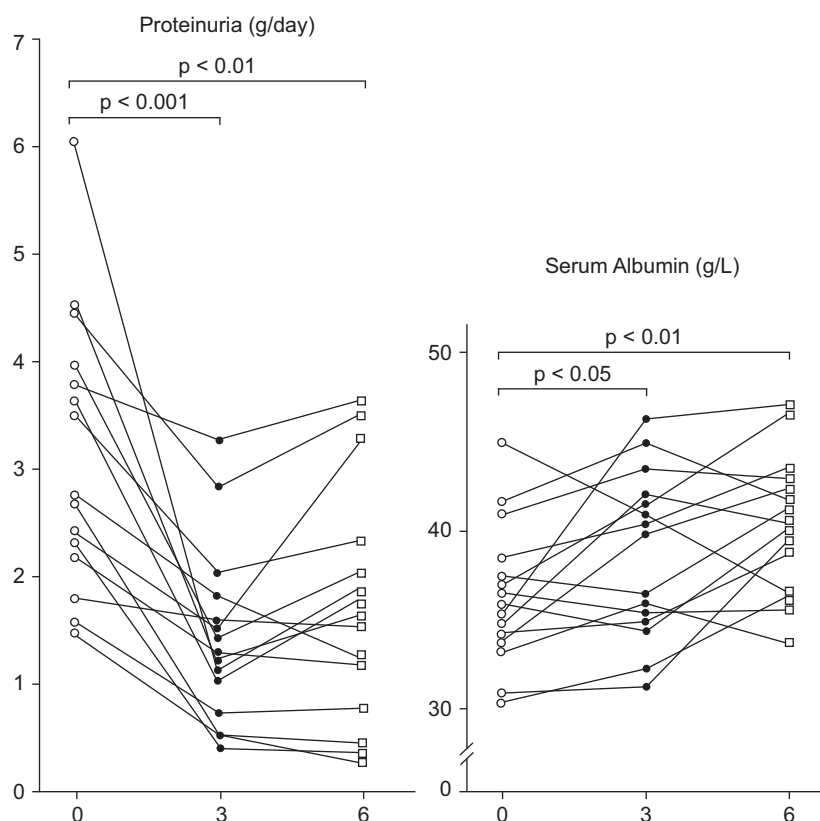

In a more recent set of experiments, Garibotto and colleagues reassessed protein metabolism at the tissue level by forearm arteriovenous phenylalanine turnover in stage 3–4 CKD patients. In two different studies, they underwent 6-week diets in a crossover design with either a normal diet (1.1 g protein/kg/day) or two different low-protein diets (0.55 and 0.45 g protein/kg/day supplemented with ketoacids). Nitrogen balance was fully maintained during the study through an adaptive reduction in amino acid oxidation during the two low-protein diets [86].

### Effects of low-protein diets on proteinuria

Since proteinuria has been clearly identified as an independent risk factor for the progression of kidney disease, it is relevant to examine the specific effects of low-protein diets on proteinuria. As discussed earlier, experimental studies almost unanimously report a reduction in proteinuria when animals are placed on a low-protein diet. In humans the acute 35% reduction in proteinuria observed by Rosenberg et al. [87] was confirmed during a longer duration of dietary therapy by Aparicio and coworkers [65]. These investigators reported a decrease in proteinuria from  $3.2 \pm 1.2$  to  $1.8 \pm 1.1$  g/day ( $P < .01$ ) in 15 patients with advanced chronic kidney insufficiency after 6 months of a very low-protein intake (0.3 g/kg/day) supplemented with ketoacids, whereas serum albumin increased concomitantly from  $36.5 \pm 4.0$  to  $40.8 \pm 3.2$  ( $P < .01$ ) (Fig. 16.4) [65].

In 12 proteinuric patients with CKD, Rosenberg and colleagues examined, in a random crossover design, the effects of a marked reduction in protein intake from 2 to 0.55 g protein/kg/day for 11 days [87]. There was a 35% decrease in proteinuria from  $7.0 \pm 3$  to  $4.7 \pm 2$  g/day, an improved glomerular permselectivity as determined by dextran clearances and from a disproportionate reduction in IgG as compared to albumin clearance, whereas there was no change in GFR and renal plasma flow [87], there was a net decrease in plasma renin activity and plasma

**FIGURE 16.4** The decrease in proteinuria (left panel, g/day) and the increase in serum albumin (right panel, g/L) during three and six months treatment with a very low protein diet (0.3 g/kg/day) in 15 patients with advanced chronic kidney disease. Source: From Aparicio M, Bouchet JL, Gin H, et al. Effect of a low-protein diet on urinary albumin excretion in uremic patients. *Nephron* 1988;50(4):288–291.

aldosterone was also noted during the low-protein period, confirming experimental data.

When Giordano et al. [82] changed seven patients with the nephrotic syndrome from a 1.2 to a 0.66 g protein/kg/day protein diet, proteinuria decreased by 38%, and there was a linear relationship between the reduction in proteinuria and the achieved reduction in protein intake, as has been previously noted by Kaysen and colleagues [88]. It was proposed that a decrease in proteinuria is a stimulus for a reduction in albumin synthesis. Furthermore, fibrinogen synthesis rate also decreased by 30% with LPDs, from 4.6 to 3.0 g/1.73 m<sup>2</sup>/day,  $P < .03$ ; these synthesis rates, however, were still increased as compared with healthy volunteers (1.93 g/1.73 m<sup>2</sup>/day) [82]. The similar reductions in albumin and fibrinogen syntheses may be triggered by a common mechanism, presently unknown, but which is advantageously modulated by a low-protein intake. Thus not only do patients with CKD generally adapt to low-protein diets but also there seem to be further benefits of such low-protein diets by reducing proteinuria and its consequent metabolic disturbances in nephrotic states. In another study, Bellizi et al. [89] reported in 110 CKD patients the effects during 6 months of three different protein intakes, 1.04, 0.78, and 0.54 g/kg BW/day, the last intake being supplemented with ketoanalogues. Proteinuria decreased significantly in the most restricted group, from 1.34 to

0.87 g/day, whereas it was not affected in the more important protein intake groups [89].

It is well established that ACE inhibitors and ARBs (angiotensin receptor blockers) markedly reduce the degree of proteinuria in most kidney diseases. Of interest is the additional antiproteinuric effect of a low-protein diet in combination with these nephroprotective medications. Ruilope et al. first described this observation in a short-term study involving 17 patients with mild CKD [90]. Enalapril, 20 mg/day, reduced proteinuria by about 20%; a 25% reduction in protein intake from 1 g/kg/day (estimated from urinary urea output) decreased proteinuria by 30%. However, the combination of both interventions induced a 55% decrease in proteinuria; this latter reduction in proteinuria was significantly greater than each separate intervention [90]. Gansevoort and colleagues [91] confirmed these findings by studying, in a crossover design, 14 patients with modest kidney impairment and nephrotic range proteinuria. Enalapril, 10 mg/day, induced a reduction of proteinuria by 35%, whereas a 50% reduction in protein intake decreased proteinuria by 20%. Again, there was an additional effect of both treatments, with a 55%–60% decrease in proteinuria by enalapril and low-protein intake. Furthermore, as shown in Fig. 16.5, there was a linear relation between the reduction in both protein intake and proteinuria [91]. A recent exhaustive

FIGURE 16.5 The linear relationship between the degree of reduction in dietary protein intake from baseline (1.0 to 1.5 g protein/kg/day) and the concomitant reduction in daily proteinuria in 14 nephrotic patients with normal to mild chronic kidney disease ( $r = 0.58$ ,  $p < 0.05$ ). Additive antiproteinuric effect of ACE inhibition and a low-protein diet in human renal disease. *Nephrol Dial Transpl* 1995;10(4):497–504.

review addressed the potential benefits of an LPD to those of ACEI/ARB-protective effects [92].

### Effects of the nature of protein intake

As previously discussed in experimental studies, the nature of protein, for example, from animal or vegetal source, may impact on the kidney response to the diet [49]. In humans, Kontessis et al. examined the effects of protein of different sources on glomerular dynamics in 17 healthy volunteers. Although diets were not heavily restricted (intakes averaged about 1 g/kg BW/day), a decrease in GFR ( $-10\%$ ), in urinary albumin excretion ( $-50\%$ ), and IgG clearance ( $-35\%$ ) was observed after 3 weeks of ingesting a vegetable protein as compared to a regular animal protein diet [93,94]. In another study of similar design, these investigators measured GFR in nine diabetic patients without severe kidney involvement [93]. Again, there was a 15% and 40% decrease in GFR and in microalbuminuria, respectively, with the vegetable protein as compared with the animal protein diet. Interestingly, a marked decrease ( $-20\%$ ) in serum IGF-1, a strong GFR regulatory hormone, was also observed with the vegetarian protein diet, thus suggesting that protein intake might regulate renal hemodynamics, at least in part, through IGF-1 levels.

Another report from Brazil tested in 17 diabetic patients in a random crossover design, the effects of three different protein diets [95]. Patients had macro

albuminuria and normal kidney function. One diet included beef protein, 1.33 g/kg/day, the second diet was composed of 1.22 g protein/kg/day from chicken meat, and the third was a low-protein diet of 0.8 g/kg/day from vegetable source. There was no change in GFR; macro albuminuria decreased from 313  $\mu\text{g}/\text{min}$  (beef) to 269 (chicken) and 229 (vegetarian),  $P < .05$ . Lipid profile improved gradually as a consequence of a reduction in saturated fatty acid from red meat to low-protein diet. The authors attributed the reduction in macro albuminuria to the vascular protective effect of the polyunsaturated fatty acid enrichment mainly found in the low-protein vegetable source diet [95].

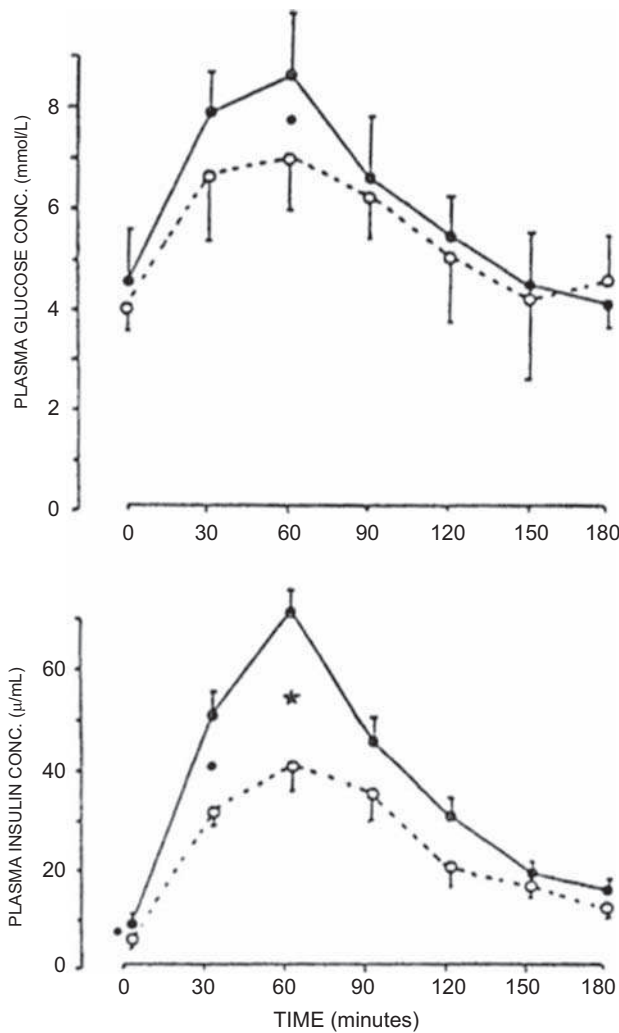

More recent data from the CRIC study addressed the metabolic effects of an increase in plant food in stage 3 CKD patients followed for 3 years. The lowest plant protein quintile group did show a higher urinary phosphate output compared with the highest plant protein intake quintile, suggesting a reduced phosphate absorption from vegetal source, whereas the total protein intake was similar between groups [96]. However, based on a large data set analysis, the recent AND/KDOQI guideline did not recommend to choose plant versus animal protein as a source of nutrients [97].

### Effect of low-protein diets on insulin resistance

Abnormal insulin sensitivity and insulin resistance can be improved by a low-protein diet. Gin and colleagues tested the effects of a very low-protein intake (0.3 g/kg BW/day) in 10 patients with nondiabetic advanced CKD (creatinine clearance: 15 mL/min) supplemented by ketoacids on serum glucose and insulin after an oral glucose test. Both serum glucose and insulin peaks were significantly reduced after 4 months of diet (Fig. 16.6), suggesting an improvement in insulin resistance [98]. In a subsequent study, these authors investigated eight patients (GFR:  $13.2 \pm 2.8$  mL/min/ $1.73$  m<sup>2</sup>) undergoing the same diet for 3 months [99]. Patients showed an improvement in fasting serum glucose from  $5.0 \pm 0.1$  to  $4.7 \pm 0.1$  mmol/L ( $P < .05$ ), a decrease in fasting plasma insulin from  $82.4 \pm 20.7$  to  $48.8 \pm 8.0$  pmol/L ( $P < .05$ ). More importantly, using the gold standard euglycemic insulin clamp, these workers showed a decrease in endogenous glucose production by 66% for comparable plasma insulin levels. These data clearly indicate an improved sensitivity to insulin in nondiabetic CKD patients [99].

### Effect of low-protein diets on dyslipidemia

As already mentioned, protein intake could be associated with different patterns of lipid intake. Mainly, meat intake brings saturated fatty acids (in pork, lamb, and beef), whereas white meat such as chicken or turkey bring less saturated fatty acids. Fish and vegetable proteins are mainly associated with

**FIGURE 16.6** The effects of a reduction in protein intake during four months on plasma glucose and plasma insulin response (oral glucose test) in 10 non diabetic CKD patients. Protein intake was reduced from baseline (1.0 protein/kg/day) to 0.3 g protein/kg/day with ketoacids supplement. Baseline: close circle, low protein diet: open circle ( $p < 0.05$ ). Source: From Gin H, Aparicio M, Potaux L, de Precigout V, Bouchet JL, Aubertin J. Low protein and low phosphorus diet in patients with chronic renal failure: influence on glucose tolerance and tissue insulin sensitivity. *Metabolism* 1987;36(11):1080–1085.

unsaturated cardiovascular protective fatty acids. In addition, cooking meat frequently bring extra lipid source and sodium chloride. As a consequence, most reports show that reducing protein intake from animal source improves lipid intake and patients lipid profile. For example, Bernard et al. reported an improvement in the ratio apoA1/apoB ( $P < .03$ ) in 11 stage 3 CKD patients after they were switched from 1.1 to 0.7 g protein/kg/day during 3 months [100]. Bellizzi and coworkers reported a 24% and 18% decrease in serum total cholesterol and triglycerides respectively ( $P < .001$ ), after 6 months of a very low-protein intake, which seems close to the effect of a statin treatment [89].

### **Effect of low-protein diets on phosphate, mineral, and bone disease**

The mineral and bone disease field has emerged as one of the most important during CKD, not only because of progressive bone frailty but also because of a partial responsibility in increased vascular calcifications. Indeed, mortality from cardiovascular disease represents approximately 50% of the overall mortality at every stage of CKD, including the dialysis and transplant ones. Since hyperphosphatemia and hyperparathyroidism are frequently observed even at early stages of CKD, improving serum phosphate has long been the goal of a targeted dietary counseling before dialysis. Finally, the discovery of fibroblast-growth factor-(FGF)23, the key factor of phosphate metabolism, has reinforced the interest for research in this field.

Phosphate is strongly linked to protein since 1-g protein brings approximately 13-mg phosphate. Not all phosphate is absorbed by the gut, only 40%–80%, and this may be influenced by the fiber content of the diet, (i.e., phosphate from vegetarian source will be less absorbed than from animal source). By contrast, calcitriol will increase the fractional rate of gut phosphate absorption. Serum phosphate will also be influenced by kidney tubular excretion and bone metabolism. The different responses of phosphate metabolism during the progression of kidney disease have been highlighted in a recent work of Isakova and colleagues who notably showed that serum FGF-23 increases long before the rise in serum PTH (parathyroid hormone). Thus the primary response to the oral phosphate intake is an increase in serum FGF-23 to maintain a sufficient tubular phosphate excretion, for example, when GFR is about 80–60 mL/min. In addition, FGF-23 blunts the activity of the  $1-\alpha$  hydroxylase, blocking the synthesis of calcitriol in the proximal tubule and, therefore, reducing gut phosphate absorption. For yet unexplained reasons, during progressive CKD, FGF-23 fails to maintain normal serum phosphate and when GFR is about 50 mL/min, serum PTH starts to rise, which, in turn, compensates kidney phosphate excretion. Finally, when GFR drops below 35 mL/min, serum phosphate increases and there is no further efficient metabolic adaptation to this rise.

Why are these changes important to be highlighted in this section? First, in addition to the phosphocalcic abnormalities, it has been recently reported that elevated FGF-23 by itself may be independently linked to a reduced survival in healthy adults and CKD patients as well [101–103]. Second, the only way yet identified to improve serum FGF-23 is the reduction in phosphate intake, for example, protein intake. Indeed, in healthy adults, it has been reported that FGF-23 expression can be directly regulated by dietary

phosphate. When adults received a daily oral load of 1-g phosphate for 5 days, serum FGF-23 increased by 30%, whereas serum PTH did not change. In response to the increased FGF-23, there was an increase in urinary phosphate excretion and a decrease in serum calcitriol, effectively counteracting the increase in dietary phosphate load [104]. Restricting dietary phosphate can also improve serum FGF-23: after 5 days of taking an oral phosphate binder, intestinal phosphate absorption decreased and urinary phosphorus excretion fell. Likewise, reducing the phosphate intake of 13 healthy men from 1500 to 625 mg/day induced a 30% decrease in serum FGF-23, suggesting that phosphate intake exerts a direct effect on FGF-23 expression [104].

Moe et al. studied in a random crossover design in nine stage 3 CKD patients the effects of two different diets with the same phosphate content, for example, 800 mg/day, one from animal source and the other from vegetarian source during 1 week [105]. They observed during the vegetarian diet phase the known reduction in urinary phosphate excretion and serum phosphate, in response to the reduced gut absorption of phosphate bound to vegetal fibers. More interestingly, they showed for the first time a significant 28% reduction in serum FGF-23 during the vegetarian cycle as compared with the animal protein phase during which FGF-23 increased by 40% ( $P < .01$ ) [105].

These data emphasize why it is mandatory to monitor the dietary habits of CKD patients. Controlling serum phosphate below 1.4 mmol/L must include a phosphate-restricted diet. The daily amount of phosphate should be 800 mg, a level that allows enough dietary variety while protecting from excessive accumulation of phosphate. If dietary proteins are not controlled, even major increase in hormones controlling serum phosphate (PTH and FGF-23) will not be able to control the development of hyperphosphatemia.

### ***Effect of low-protein diets on acidosis, anemia, and blood pressure***

There are subsequent indirect beneficial effects of a reduction in protein intake during CKD on metabolic acidosis, hemoglobin status, and blood pressure control. Indeed, Chauveau et al. showed that there is an inverse relationship between protein intake and serum bicarbonate in a cross-sectional survey of more than 7000 hemodialysis patients [106]. In 10 stage 5 CKD patients receiving a supplemented very low-protein diet (VLPD) during 12 months, the same investigators showed an increase in serum bicarbonate from 24.2 to 26.5 mmol/L,  $P < .05$  [107]. From the MDRD study, Mitch and Remuzzi also estimated that a reduction in 0.20 g protein/kg/day significantly increased serum bicarbonate ( $P < .05$ ) [108]. These changes mainly

pertain to the acidotic nature of animal protein, which was long identified by Claude Bernard in the late 1800s. Moving to vegetal protein will induce alkalotic urine, as observed in the majority of ruminant species. In light of recent De Brito's English trial, which convincingly demonstrated improvement in patients body composition and slowing of kidney disease progression after administering oral sodium bicarbonate [109], it may be also metabolically worth reducing animal proteins to increase serum bicarbonate.

Anemia control maybe improved while reducing protein intake. Indeed, Di Iorio et al. observed an improvement in hemoglobin levels in a random trial in 20 MHD patients receiving either a low-protein intake or a VLPD supplemented with ketoacids [110]. In the VLPD group, serum hemoglobin remained stable and erythropoietin dose could be decreased by approximately 35% during the 2-year duration of the trial. These investigators revealed a strong and inverse relationship between the change in patients' hemoglobin levels and serum parathormone, which is not unexpected since parathormone is responsible for a well-described resistance to the EPO (erythropoietin) effects on bone marrow. Improvement in parathormone was the consequence of the reduction of the dietary phosphate load and possibly to the calcium intake associated with the ketoacids. VLPDs should, therefore, be credited for these beneficial effects, although they could be considered as indirect.

Finally another dietary change that can be viewed positive is the fact that lowering animal protein will also reduce sodium intake, since most culinary habits do add salt while cooking meat. In the ERIKA study, a 6-month trial comparing three different levels of protein intake in [110] stage 4–5 CKD patients, Bellizzi et al. showed a positive relationship between 24-hour urinary sodium and urinary urea excretion, indicating that patients who ate less proteins had the most important reduction in sodium intake, and a better reduction in blood pressure [89]. As a consequence, patients will improve their blood pressure control and reduce their daily pill burden.

### ***Nutritional safety of restricting protein intake***

The question of whether LPDs are safe has been a subject of some controversy [111] and has been examined by estimating the nutritional status and survival of patients who received reduced protein intakes for years. Chauveau et al. [107] reported regional body composition measured by DEXA (dual x-ray absorptiometry) and nutritional status in 10 patients receiving a VLPD (0.3 g protein/kg/day supplemented with amino acids and ketoanalogues) for 1 year. There was no change in anthropometric measures and serum biochemistry during the 1-year follow-up [107]. DEXA

analyses revealed a decrease in lean body mass during the first 3 months following the reduction in protein intake that was not fully corrected to baseline at 1 year (baseline: 46.2 kg; 1 year: 45.1 kg). Body fat mass increased slightly at 3 months and 1 year (baseline: 20.1 kg; 1 year: 21.4 kg,  $P < .01$ ). Interestingly, there seemed to be a redistribution of lean body mass in favor of an increase in lean truncal mass, which was sustained during the 1 year of follow-up [107]. It should be mentioned that during this trial, energy intake was  $27.8 \pm 7.6$  at baseline,  $31.0 \pm 8.1$  at 3 months, and  $29.8 \pm 8.8$  kcal/kg/day at 1 year. Thus the alterations observed after 3 months of a very low-protein intake spontaneously improved over time, became of no clinical importance after 1 year of follow-up, and occurred in association with the benefits observed with regard to insulin resistance, bone metabolism, and reduction in uremic symptoms [107]. Long-term low-protein interventions have also been reported to be safe by other investigators [112–116]. In the MDRD study, body weight and composition were assessed every 3 months during the 2.2-year mean follow-up period [116]. The actual reductions in protein intake were less than expected (actual vs prescribed: 0.71 vs 0.58 and 1.11 vs 1.3 g/kg BW/day, respectively, in Study A; 0.48 vs 0.28 and 0.72 vs 0.58 g/kg BW/day, respectively, in Study B). Furthermore, energy intake was low despite intensive counseling (range: 22.5–26.7 kcal/kg/day among different subgroups). Despite these values, overall clinical and biological surveys, as well as end point recording did not show evidence for nutritional impairment during a follow-up period of 2–3 years [116]. Fig. 16.7 shows that serum albumin levels increased slightly in all groups from baseline, but this increase was greater in the low-protein diet group as compared with the control group in Study A (Fig. 16.7, top, solid line). The decrease in serum transferrin during the study is somewhat difficult to interpret, because iron stores and the presence of inflammation were not monitored. Finally, although statistically significant, these changes in body composition may not be of clinical importance (–2 to 0 kg for body weight and –0.5 to +0.5% for body fat mass over 3 years). They underscore the importance for the physician to ensure that there is adequate nutritional monitoring and, where indicated, nutritional intervention in these patients (Table 16.1). Importantly, no patient had to withdraw from the MDRD study because of impaired nutritional status.

The recent AND-KDOQI guideline assessed the nutritional safety of low-protein diets and concluded that neither low-protein diets nor supplemented VLPDs have been associated with impairment in nutritional status assessed by anthropometry, subjective global assessment, or serum albumin [97]. There was only 1

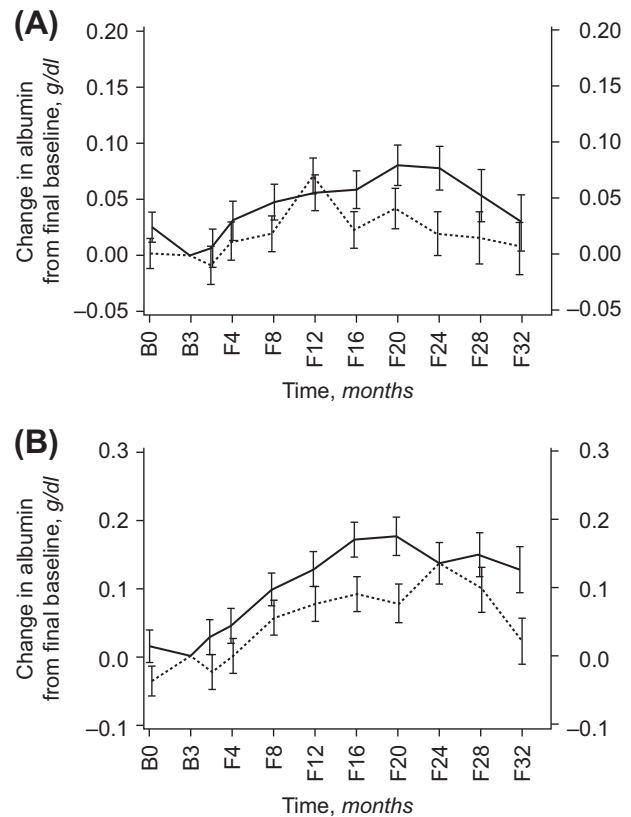

FIGURE 16.7 Mean changes in serum albumin from the end of Baseline in Study A (top) and Study B (bottom) patients during the course of the Modification of Diet in Renal Disease Study. DPI =  $7.25 \text{ UNA} + 10.9 = 45.7 \text{ g/day}$

DPI/kg =  $45.7/70 = 0.65 \text{ g/kg}$

Compliance to the diet, for example, an upper actual protein intake no greater than 20% above prescribed intake, is considered acceptable if this patient presents a UNA no greater than 5.5 g/day.

From Kopple J.D., Gao Z.L., Quing .D.P., *Kidney Int* 1997;52:486–94.

study among 26 randomized controlled trials that reported a significant loss in body weight (lean and fat mass) [112]. Nutritional status was also assessed by Hahn et al. in a recent Cochrane systematic review (see later) in which weights were available in more than 500 patients, and it was concluded that no significant change in body weight occurred during a follow-up of 12–50 months [1].

What is the long-term consequence of low-protein diets on survival after dialysis therapy is started?

Walser et al. demonstrated that patients ingesting a VLPD who were carefully followed before they commenced dialysis treatments could postpone dialysis for many months, even with very low GFRs, before clinical symptoms occurred [117,118]. Aparicio and colleagues reported encouraging outcomes in 165 maintenance dialysis patients who were treated with VLPDs before they developed end-stage kidney disease [115]. Chauveau et al. more recently reevaluated 203 patients long-term survival after they started maintenance dialysis or received a kidney transplant [119,120]. Analyzing these patients with an unbroken follow-up during 10 years after the start of replacement therapy, these authors clearly showed that patients who received an SVLPD (supplemented very low protein diet) before ESRD (end stage renal disease) had a survival as good as patients without specific diet as reported in the French Dialysis registry, for example, 79% at 5 years and 63% at 10 years [120]. Their results stand in contrast with those of Menon et al. who reanalyzed the late patients' survival of the supplemented VLPD subgroup of the MDRD study [121]. Although patients who received the SVLPD had a poor survival 7 years after the termination of the MDRD study, there was no clinical or biological information on patients to document survival during those 7 years and it is difficult to incriminate 30 months of well-followed dietary intervention versus 80 months of virtually unknown follow-up [119].

### Clinical evidence of the effects of low-protein diets

For many years, it has been proposed that patients with advanced kidney disease should reduce their protein intake to decrease uremic symptoms. In the mid-1970s, since a number of experimental studies reported beneficial effects of low-protein intakes on kidney function, it was proposed to test this hypothesis in humans. Before analyzing in detail these studies, some general remarks should be made. First, as discussed earlier, most animal research studies were performed using extremely high or low levels of dietary protein (e.g., unphysiological or very large differences in dietary protein content between groups), to identify mechanisms and explain therapeutic effects. Second, in many experiments, substantial numbers of animals died without analysis of the potential role of the diet in these deaths. Only data from the survivors were analyzed, a fact that would not apply to human research. Third, most laboratory research is short-term, in animals that do not have other chronic diseases, by contrast with many patients presenting with CKD. Thus the issue of low-protein diets in CKD patients

may differ from experimental studies. Indeed, as compared with experimental research, there are specific caveats to clinical research, such as the variability of outcome, the issue of treatment compliance and medication effects, and, eventually, the phenotype of the population studied. These factors are among reasons why such large numbers of patients are required to test a single hypothesis in a clinical trial.

### Clinical trials and cohorts

A recent prospective observational study in France followed more than 1400 CKD stage 3–4 patients over 3 years [78]. No specific dietary counseling or nutritional target was provided. The number of patients starting maintenance dialysis was inversely related to the daily protein intake which was reliably assessed by both dietary reports and urinary nitrogen output. Patients with an average protein intake of 0.6 g/kg/d had a 25% lower dialysis need compared with those ingesting 1.2 g/kg/day [78] (Fig. 16.8).

More than 55 prospective clinical trials have assessed the effects of low-protein diets in humans with kidney disease. These studies have been analyzed in a recently updated review [1]. However, in many of these trials, the methodological quality was judged to be poor, based on uncontrolled design, nonrandom

FIGURE 16.8 The inverse relationship between daily protein intake estimated by urinary nitrogen output and the hazard ratio for starting maintenance dialysis in the NephroTest prospective cohort. allocation of diets, or the use of retrospective analyses. Furthermore, many of these reports, undertaken in the early 1970s, did not use an adequate marker of renal function to assess the effect of the diet intervention, particularly since the serum creatinine or its derivatives (creatinine clearance, 1/serum creatinine) are strongly influenced by the primary intervention, for example, reducing protein intake (see earlier). Since contradictory results were often reported, we only reviewed the largest trials of high methodological quality, that is, those large prospective, controlled trials with a random allocation of diet intervention.

The Northern Italian Cooperative Study Group, in 1991, reported the results of a large randomized controlled study in 456 patients with a GFR lower than 60 mL/min, who were followed for 2 years [122]. Patients either received a control protein intake of 1 g/kg/day or a low-protein intake providing 0.6 g/kg/day, both diets provided an energy intake of at least 30 kcal/kg/day. The main outcome criterion was the renal survival defined as the start of dialysis therapy or the doubling of serum creatinine during the trial. Dietary protein intake was serially monitored by urinary urea output in a random sample of patients. Actual protein intakes were, however, poorly different since the control group did eat 0.90 g protein/kg/day and the low-protein group 0.78 g/kg/day, and there was a large overlap between individuals from both groups (underlining the necessity for intensive dietary counseling and monitoring). There was only a borderline significant difference between control and restricted protein groups with slightly less patients in the latter group reaching a renal end point ( $P = .059$ ).

The MDRD study was the largest clinical study yet performed to test the effects of low-protein intake and strict blood pressure control on the progression of kidney disease in more than 800 patients [71,123–130].

Two groups of patients were studied, one with moderate kidney dysfunction (Study A, GFR: 25–55 mL/min/1.73 m<sup>2</sup>) and the second with a more advanced kidney dysfunction (Study B, GFR: 13–24 mL/min/1.73 m<sup>2</sup>). The patients were randomized to receive 1 g protein/kg/day or more versus 0.6 g/kg/day and to reach a mean blood pressure of 105 or 92 mmHg in group A, and 0.6 g protein/kg/day versus 0.3 g/kg/day plus a ketoacid supplement and comparable blood pressure goals in group B. The primary objective was the effect of both interventions, in a Latin square design and intention-to-treat analysis, on the progression of kidney disease. This was estimated by the changes in 125I-iothalamate clearance measured every 4 months over more than 2 years. The mean patient follow-up was 2.2 years [126]. Actual protein intakes were  $1.11 \pm 0.19$  versus  $0.73 \pm 0.15$  g protein/kg/day in group A ( $n = 585$ ), and  $0.69 \pm 0.12$  versus  $0.46 \pm 0.15$  g protein/kg/day in group B ( $n = 255$ ). The overall results appeared at first glance somewhat disappointing. There was no difference between the groups with regard to the decline in GFR in Study A. In Study B, there was a borderline significantly greater rate of decline in GFR in the group prescribed the 0.6 g protein/kg/day diet versus the ketoacid supplemented diet ( $P = .07$ ).

These raw results require several comments. First, as shown in Fig. 16.9, during the first 4 months of diet intervention in Study A, there was a sharp initial decrease in GFR in the group with the more restricted protein intake (mean DPI, 0.73 g/kg/day). This was followed by a slower linear decrease than occurred with the larger protein intake (mean DPI, 1.11 g/kg/day). This initial 4-month decrease in GFR with the lower DPI is now considered to be the consequence of the reduction in glomerular hemodynamics that

FIGURE 16.9 The GFR decline during the course of the Modification of Diet in Renal Disease Study (Study A) with separate analyses including or not the first 4-month adaptation period. GFR, Glomerular filtration rate. Source: From Levey AS, Greene T, Beck GJ, et al. Dietary protein restriction and the progression of chronic renal disease: what have all of the results of the MDRD study shown? *Modification of Diet in Renal Disease Study group. J Am Soc Nephrol* 1999;10(11):2426–39 with permission.

follows protein restriction [28]. Arguably, in retrospect, there should have been a run-in period that included the first several weeks of dietary protein treatment before the key GFR outcome data began to be collected. If this had been done, the follow-up period of the study, for example, from 4 months after the start until 3 years, the slope of GFR decrease, which was significantly lower in the more restricted protein group (Fig. 16.9,  $P = .009$ ) [130], would have indicated a beneficial effect of dietary protein restriction in reducing the rate of decrease in GFR. Second, unexpectedly, the actual rate of progression of kidney failure was lower than expected when the study was designed (i.e., in Study A, the reduction in GFR was 3.8 vs 6 mL/min/year) [124]. This had a major negative impact on the ability of this study to demonstrate statistical differences. An additional 3-month period of follow-up would have been necessary to correct for this reduction in GFR decline. Thus it is tempting to classify this large clinical trial as inconclusive rather than negative. In addition, when patients were followed in an open fashion after the end of the study and up to 44 months of diet, the difference in cumulative incidence of ESRD or death reached borderline significance in the patients who were assigned to the lower protein diet ( $P = .056$ , Fig. 16.10). It should be remembered that in the large diabetes DCCT trial for strict blood glucose control and its effects of kidney impairment, no effect was detected at 2 years, and the suppressive effect of strict glucose control on the development of microalbuminuria or proteinuria was only observed after 4 years of treatment [131].

Although not definitive, correlational analyses may give further insights into the efficacy of dietary intervention, particularly when a flawed design, such as an

observation period of inadequate duration, hampers the interpretation of the main outcome measure. First, when patients were analyzed with regard to their actual protein intake, as estimated through either diet interviews and diaries or urea nitrogen appearance, and independently of the group to which they were randomized, a strong relation was found between the magnitude of protein intake and the GFR slope ( $P = .011$ ) or renal death (e.g., risk of death or ESRD) ( $P = .001$ ) [130]. Indeed, for Study B, a regression model estimated that for every reduction in 0.2 g protein/kg/day, there was a 1.15 mL/min/year reduction in GFR decline and a 49% reduction in the incidence of renal death [130]. There was no additional effect of ketoanalog supplements on retardation of progression of renal failure. This finding contradicts a previous observation made in the MDRD Feasibility Study in which a trend for a protective effect ( $P = .06$ ) of ketoacids was observed [129]. These latter authors suggested that the different ketoanalog composition used in the MDRD Study B, and particularly the greater tryptophan content, may account for the lack of effectiveness of the ketoacids in the MDRD study [129,132].

A comparable analysis in Study A showed a more moderate impact of protein restriction with a 0.32 mL/min/year slower GFR decline per each 0.2 g protein/kg/day reduction ( $P = .075$ ). Thus these secondary analyses of the MDRD study tend to support a moderate beneficial effect of reduced protein intakes in patients with CKD; these effects were related, in a gradient fashion, to a reduction in the protein intake rather than to a well-identified degree of protein restriction that was necessary to slow progression. There was no apparent effect of either protein intake or blood pressure control in patients with polycystic kidney disease. Since these individuals constituted 25% of the total patients in the MDRD study, this fact also contributed to the ambiguous results of the MDRD study [133].

More recently, Garneata et al. [134] reported an elegant randomized controlled trial in 207 stage 4 CKD patients, with a GFR of  $18 \pm 3$  mL/min, treated during 15 months. There was a two-steps selection of patients, one to identify those patients who would be able to comply with a protein restriction (782 among 1413 patients), and then a 3-month run-in period with a vegetarian diet test. After this test diet, only 207 patients qualified to enter the study and were randomized to receive a diet of 0.6 g protein/kg/day (control arm) or a 0.3 g protein/kg/day supplemented with a mixture of amino acids and ketoacids (0.125 g/kg/day) (intervention group). Energy intake was reported to be 30 kcal/kg/day during the entire study in both arms. It is important to note that after randomization, there was a 3-month initial adaptation period after which all measures started to be recorded for a further 12-month assessment time. This point is of major importance to allow the body to adapt to the

FIGURE 16.10 Occurrence of renal failure or death in Study A of the Modification of Diet in Renal Disease Study, including a 10-month additional follow-up after completion of the study ( $P = .056$  between the two levels of protein intake). Source: From Levey AS, Greene T, Beck GJ, et al. Dietary protein restriction and the progression of chronic renal disease: what have all of the results of the MDRD study shown? hemodynamic and nutritional changes that occur after changing the protein intake. This aspect was not considered during the MDRD study (Fig. 16.9) and was primarily responsible for the 128 negative results published in the initial MDRD study report [126].

The study showed a beneficial effect of a very low vegetarian supplemented protein intake (VLPD) with 13% of patients reaching the end point (dialysis initiation or a >50% reduction in GFR) versus 42% in the LPD group ( $P < .001$ ). Dialysis initiation alone was reported in 11% (VLPD) versus 30% (LPD), ( $P < .01$ ). The prescription of nephroprotective medications (ACEI and ARB) was similar (approximately 70%) in both groups during the entire study. A detailed nutritional assessment did not report any difference in subjective global assessment, body mass index, anthropometry measures, serum albumin, and potassium. Acid–base metabolism was improved since serum bicarbonate rose from 16.7 to 22.9 mmol/L ( $P < .01$ ) and bicarbonate supplements were noticeably reduced ( $P < .01$ ) in the VLPD group as compared with the LPD group. Serum calcium and phosphate were also better maintained in the VLPD group during the entire study. Only 3% of patients left the study in equilibrium between groups.

## Metaanalyses

Metaanalysis is a comprehensive method aimed at searching, selecting, and analyzing appropriately designed clinical trials to increase the number of patients or observations and improve the power of statistical analysis [e.g., by reducing the confidence interval (CI)] [1,135,136]. To date, metaanalyses are considered to be second in validity of the evidence it provides, immediately behind the evidence provided by large randomized trials (considered to be level one), and equal to small randomized trials [137]. Three metaanalyses have been performed on low-protein diets [1,138–140]. These reports have searched the literature by different ways to ensure the most exhaustive collection of trials, including international databases in non-English languages. The most rigorous criteria for selecting or rejecting papers for analysis include consideration of randomized controlled trials only, since it is generally believed that nonrandomized controlled trials are more likely to give biased results than their randomized counterparts [140].

In an attempt to examine the impact of low-protein diets on loss of GFR, Kasiske and associates summarized a total of 24 controlled clinical trials, of which 13 were randomized [140]. The main outcome was the loss of GFR over time (mL/min/year) in groups receiving or not a low-protein diet. A total of 2248 patients were

collected from which 1919 were enrolled in randomized studies. GFR loss was lower by 0.53 mL/min/year (95% CI, 0.08–0.98) in the lower protein intake group ( $P < .05$ ).

Based on this background, we identified 17 randomized controlled trials, including 2996 patients suitable for analysis, among 133 reports of clinical trials assessing the effects of low-protein diets for the treatment of patients with chronic kidney insufficiency [1]. Gender and the nature of kidney disease were equally distributed in control and more restricted groups; thus these avoiding well-identified independent causes for more rapid progression of kidney disease would not influence the results.

In the low-protein intake subanalysis, there were 904 patients with a low-protein intake (0.5–0.6 g protein/kg/day) and 910 individuals with a normal protein intake. In the low-protein diet group, 130 dialysis starts were found, while 131 in the larger protein intake group, giving a nonsignificant odds ratio of 1.05, CI 0.73–1.53 ( $P = \text{NS}$ ). In the very low-protein intake subanalysis, there were 508 patients with a very low-protein intake (0.3–0.4 g protein/kg/day) and 502 individuals with a low-normal protein intake (Fig. 16.11). In the VLPD group, 158 dialysis treatments were found, while 230 in the larger protein intake group, giving an odds ratio of 0.64, CI 0.49–0.85 ( $P = .0019$ , Fig. 16.11). This indicates that a very low protein diet resulted in a 36% reduction for starting dialysis as compared with larger or unlimited protein intakes [1]. It also suggests that a moderately reduced protein intake may not be protective enough and a better metabolic control may be obtained by a very low protein diet, thus postponing the need for dialysis. Interestingly, it should be noted that the nutritional status of patients was also assessed. Body weight changes were pooled as well as protein energy wasting and no signs of weight loss ( $n = 514$  patients) or declared protein energy wasting ( $n = 2373$  patients) were reported in patients whose nutritional data were available [1].

In patients with diabetes and kidney disease (DKD), the situation is less clear. Previous guidelines recommended a protein intake of 0.8 g/kg body weight/day in patients with CKD stages 1–5. However, the KDIGO guidelines suggested more liberalization with protein restriction and recommended that 0.8 g/kg body weight/day be maintained and avoiding levels above 1.3 g/kg/body weight. Ko et al. conducted an extensive review of existing guidelines and original research in patients with DKD and indicated that a dietary protein intake of 0.8 g/kg body weight/day was advised for DKD not on dialysis [141]. However, due to the fact that uremic toxins accumulate in DKD patients as well and may increase insulin resistance, and these patients do not have increased protein

**FIGURE 16.11** A systematic review of the results from randomized controlled studies of the influence of very low protein diets in delaying the start of maintenance dialysis. A square denotes the odds ratio (treatment/control) for starting dialysis for each trial, and the diamond indicates the combined results of all trials; 95% CIs are represented by horizontal lines. Studies included a very low-protein intake (0.3–0.4 g protein/kg/day) compared to a greater amount of dietary protein (0.5–0.6 g protein/kg/day or a free diet). Overall, the “common” odds ratio = 0.64 (95% CI: 0.49, 0.85),  $P = .0019$ . CI, Confidence interval. Source: From Hahn D, Hodson EM, Fouque D. ### BOX 16.1

#### AND-KDOQI energy and protein requirements [97]

**Energy intake** In adults with CKD 1–5D (1C) who are metabolically stable, we recommend prescribing an energy intake of 25–35 kcal/kg/day based on age, gender, level of physical activity, body composition, weight status goals, KD stage, and concurrent illness or the presence of inflammation to maintain normal nutritional status.

**Protein restriction, nondialysis, nondiabetic.** In adults with CKD 3–5 who are metabolically stable, we recommend, under close clinical supervision, protein restriction with or without ketoacid analogs, to reduce risk for ESRD/death (1A) and improve QoL (quality of life) (2C).

- a low-protein diet providing 0.55–0.60 g dietary protein/kg ideal body weight/day, OR;
- a VLPD providing 0.28–0.43 g dietary protein/kg ideal body weight/day with additional ketoacid/ amino acid analogs to meet protein requirements (0.55–0.60 g/kg body weight/day).

**Protein restriction, nondialysis, diabetic.** In the adult with CKD 3–5 and who have diabetes, it is reasonable to prescribe, under close clinical supervision, a dietary protein intake of 0.6–0.8 g/kg ideal body weight per day to maintain a stable nutritional status and optimize glycemic control (OPINION).

needs, the recent AND-KDOQI guideline advised for a protein intake of 0.6–0.8 g/kg/day [97] (Box 16.1).

Finally, the number needed to treat (NNT), a methodological tool, is routinely used to compare the efficacy of a given treatment in different studies [142].

It theoretically represents the number of patients that must be treated by a given intervention to avoid one extra death or a prespecified event per year. From the previous metaanalysis data [138], NNT conferred by a low-protein intervention stands between 2 and 56,

depending on the study. For example, NNT was estimated to be 4 in the most recent Garneata study [143], a very low number that favorably compares with the well-accepted mortality reduction obtained by statins in the 4S trial (NNT = 30) and WOSCOPS study (NNT = 111) [144]. This analysis gives further support to the thesis that dietary protein restriction is an effective therapeutic intervention.

## Conclusion

Many experimental studies provide evidence for the beneficial effects of low-protein intakes. These benefits include reduction in uremic toxicity, healthier nutritional status, particularly if energy intake is well maintained, reduced proteinuria and slowing of the loss of kidney function and finally delay the need for kidney replacement therapy. These results have been observed with a fairly good level of evidence in large clinical trials, systematic reviews, and guidelines, all recently updated [1,97,134,145]. Such low-protein diets, of course, do not prevent the loss of kidney function in patients with rapidly progressive kidney disease. Thus in all other patients with CKD, it may be worth prescribing a reduction in dietary protein intake.

# Disorders of phosphorus homeostasis: emerging targets for slowing progression of chronic kidney disease

Orlando M. Gutiérrez<sup>1,2</sup>

<sup>1</sup>Division of Nephrology, Department of Medicine, School of Medicine, University of Alabama at Birmingham, Birmingham, AL, United States <sup>2</sup>Department of Epidemiology, School of Public Health, University of Alabama at Birmingham, Birmingham, AL, United States

## Introduction

Rates of cardiovascular disease events and death increase in a linear fashion as kidney function declines [1,2]. This supports an emphasis on uncovering potentially modifiable risk factors for kidney disease progression in individuals with early stages of chronic kidney disease (CKD) in the hopes that slowing progression will improve long-term outcomes. To date, however, relatively few factors have emerged as effective targets for slowing the progression of CKD, representing an important unmet need in nephrology research.

High serum phosphorus concentrations are an established risk factor for cardiovascular disease events and death, particularly among individuals with CKD [3–6]. Although the mechanisms for these associations remain incompletely understood, a considerable body of evidence suggests a direct causal relationship between higher serum phosphorus concentrations and cardiovascular disease [7–12]. In addition, excess phosphorus stimulates the secretion of hormonal regulators of phosphorus metabolism such as parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23) [13–15], elevated circulating concentrations of which have emerged as robust risk factors for cardiovascular disease events and mortality [3,16–18]. Phosphorus excess has been implicated in the pathogenesis of kidney injury via similar mechanisms [19–37], suggesting that disorders of phosphorus metabolism may be promising therapeutic targets for

attenuating kidney function decline in CKD patients. Since excess dietary phosphorus intake plays a central role in the pathogenesis of disordered phosphorus homeostasis in CKD, these findings have fueled renewed interest in restricting dietary phosphorus consumption and intestinal phosphorus absorption as a potential therapy for preserving residual kidney function in CKD patients. The focus of the current section will be to review the evidence both supporting and refuting this possibility, critically appraise current recommendations for restricting phosphorus intake in CKD, and consider the next steps required to establish the efficacy and feasibility of dietary phosphorus restriction for the preservation of kidney function in CKD patients.

## Role of dietary phosphorus intake in disturbances of mineral metabolism in CKD

Serum phosphorus concentrations represent a highly dynamic balance between dietary phosphorus absorption, urinary phosphorus excretion, and exchanges with bone, soft tissue, and intracellular stores [38]. The kidneys are the primary organs that regulate this balance by modulating urinary phosphorus excretion in response to changes in diet intake and bone/soft tissue turnover. Under normal conditions, diet intake makes up the majority of the obligate phosphorus load

(1200–1500 mg/day in a typical westernized diet) that the kidneys must eliminate on a daily basis to maintain phosphorus balance [39]. As such, dietary phosphorus absorption is the primary target of therapeutic interventions aimed at mitigating the development of hyperphosphatemia in patients with CKD.

Dietary phosphorus is well absorbed across the entirety of the intestinal tract by a combination of passive paracellular diffusion and active transport across luminal sodium–phosphorus cotransporters type II (Npt2b) and type III (Pit1) [40]. Although passive diffusion in the duodenum and jejunum appears to be the primary route of dietary phosphorus absorption, studies in Npt2b knockout mice revealed that sodium-dependent active transport may account for as much as 45%–50% of total intestinal phosphorus transport [41]. 1,25-Dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ) enhances active intestinal phosphorus absorption by stimulating Npt2b expression [42]. However, unlike its role with calcium,  $1,25(\text{OH})_2\text{D}$  is not essential for the absorption of phosphorus from the intestinal lumen since passive paracellular routes of diffusion allow for substantial dietary phosphorus absorption even in settings of profound  $1,25(\text{OH})_2\text{D}$  deficiency [40].

Most circulating inorganic phosphorus is freely filtered in the renal glomeruli and enters renal proximal tubules. Under typical dietary conditions, 80%–90% of the filtered load is reabsorbed across sodium–phosphorus cotransporters 2a and 2c (Npt2a and Npt2c) in proximal tubular cells (as well as other minor transporters), and the rest is excreted in the urine [43]. PTH and FGF23 are the primary hormones that regulate the fraction of filtered phosphorus that is reabsorbed in renal proximal tubules. Both the hormones do so by downregulating sodium–phosphorus cotransporters in renal proximal tubule cells, thereby decreasing tubular phosphorus reabsorption and augmenting urinary phosphorus excretion [39,44]. In addition, FGF23 limits dietary phosphorus absorption by lowering  $1,25(\text{OH})_2\text{D}$  concentrations via the inhibition of 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase, which converts 25(OH)D to  $1,25(\text{OH})_2\text{D}$ , and by the stimulation of 24-hydroxylase, the major catabolic pathway for  $1,25(\text{OH})_2\text{D}$  [44].

Increased phosphorus intake stimulates the secretion of PTH and FGF23, which mitigates hyperphosphatemia by enhancing urinary phosphorus excretion and, in the case of FGF23, by limiting dietary phosphorus absorption via lowering  $1,25(\text{OH})_2\text{D}$  levels [13–15]. This appears to be particularly critical for maintaining phosphorus homeostasis in CKD patients in whom elevations in FGF23 and PTH play a key role in enhancing per-nephron urinary phosphorus excretion in the face of unrestricted phosphorus intake. A number of observations support this view. In a study of 404

patients with stage 3 or 4 CKD and secondary hyperparathyroidism randomized to either cinacalcet or placebo for 32 weeks, cinacalcet-treated patients had a 43% decrease in mean serum PTH concentrations but at the price of a 21% increase in mean serum phosphorus concentrations, due mainly to diminished urinary phosphorus excretion as a consequence of the decreased PTH [45]. Similarly, in a study of rats with experimentally induced kidney disease, intravenous injection of anti-FGF23 antibodies resulted in a decrease in urinary fractional excretion of phosphorus via lowering FGF23 levels and, consequently, a marked elevation in serum phosphorus [46], underscoring the critical importance of elevated FGF23 levels in the control of serum phosphorus in CKD. When these data are coupled with animal and human studies showing that the restriction of dietary phosphorus absorption decreased, and in some cases normalized, FGF23 and PTH levels in CKD [47–57], these findings support the concept that dietary phosphorus intake plays a pivotal role in the pathogenesis of disordered phosphorus metabolism in CKD.

### Disorders of phosphorus homeostasis and kidney disease progression

Phosphorus excess has long been implicated in the pathogenesis of kidney disease through a variety of proposed mechanisms (Table 17.1). In a series of experiments conducted in the 1930s, rats fed with normal kidney function diets containing markedly high amounts of inorganic phosphorus (ranging from 2% to 6.5%) for about 6 weeks developed renal tubular necrosis, diffused renal parenchymal calcification, inflammation, and associated interstitial fibrosis [58]. These effects appeared to be accentuated in the setting of kidney disease. In a classic study published by Ibels and colleagues in 1978, two groups of rats underwent subtotal nephrectomy to induce chronic uremia, after which they were fed a diet containing either a standard amount of phosphorus (0.5%) or a low-phosphorus content (0.04%) plus aluminum hydroxide for a total of 6 weeks [27]. Importantly, both diets contained similar amounts of protein. While mean serum creatinine concentrations increased to a similar degree in both groups of rats 4 weeks after the induction of kidney disease, creatinine concentrations continued to increase afterwards in the rats placed on a standard phosphorus diet, whereas they remained stable in rats placed on a phosphorus-depleted diet. In addition, all 26 animals placed on the standard phosphorus diet died prior to the end of the 6-week experimental period, whereas only 3 of the 12 animals fed the phosphorus-restricted

**TABLE 17.1** Proposed mechanisms underlying a link between excess dietary phosphorus intake or serum phosphorus concentrations and kidney disease progression.

Mechanisms	Comments
Precipitation of calcium–phosphorus microcrystals into renal parenchyma	Most common pattern of injury noted in animals fed with high-phosphorus diets; induces interstitial fibrosis, tubular atrophy, and proteinuria [25–27,29,31,33]
Stimulation of phosphaturic hormones, such as parathyroid hormone and fibroblast growth factor 23	Higher concentrations of parathyroid hormone have been associated with increased cytosolic-free calcium in renal tubules [30]; higher fibroblast growth factor 23 concentrations have been independently associated with faster kidney disease progression in observational studies [17,18,24,59]
Promotion of vascular calcification	High-phosphorus intake and excess serum phosphorus concentrations have been linked to vascular calcification in the aorta, major branch vessels, and peritubular and capillary vessels within the kidneys [26,27,31]
Stimulation of inflammatory pathways	Inflammation has been causally implicated in the nephrotoxicity of excess phosphorus intake in animal models of immune-mediated glomerulonephritis [28]

diet died. Histological examination of kidney tissue obtained *ex vivo* revealed significantly higher calcium and phosphorus content and interstitial fibrosis in kidneys from rats fed with the standard phosphorus diet as compared to the phosphorus-depleted diets, consistent with a direct pathological effect of excess phosphorus load on renal parenchyma.

Subsequent studies showed very similar findings in other rat models of kidney disease [26,28,29,31], and in studies using oral phosphorus binders instead of dietary phosphorus reduction as the primary method of limiting intestinal phosphorus absorption [33]. High-phosphorus consumption has also been shown to have deleterious effects on kidney function in companion animals, such as dogs and cats [22,23,60]. In cats with normal kidney function, very high-phosphorus consumption (five-times above maintenance requirements) resulted in higher levels of urinary albumin excretion and glycosuria as compared to cats maintained on normal phosphorus consumption [61]. In line with these findings, lower phosphorus intake lowered the degree of kidney calcification in growing kittens at the cost of a slight decrease in weight gain and in tibia length [62] and reduced the development of urolithiasis in healthy adult cats [63]. These findings may be particularly important for cats, which have a relatively high incidence of CKD [64], in part, due to the development of nephrocalcinosis with aging [65]. Reduction in phosphorus consumption was also shown to reduce kidney calcification in rabbits without compromising normal growth patterns [66]. Dietary phosphorus restriction appears to be particularly beneficial in companion animals with kidney disease. Lower phosphorus consumption slows kidney disease progression in both dogs and cats with established kidney disease and also seems to prolong survival [22,23,60]. Notably, a number of these studies showed that animals fed with

phosphorus-restricted diets had slower kidney disease progression than animals fed with phosphorus-replete diets despite no differences in the intake of protein or other nutrients [23,27,28,31], indicating that phosphorus restriction may have salutary effects on kidney function preservation independent of the known beneficial effects of protein restriction [67].

Although the impact of phosphorus excess on CKD progression in humans has been examined in less detail, some data suggest that phosphorus overload contributes to kidney function decline. Large observational studies showed that higher serum phosphorus concentrations were associated with faster kidney disease progression and higher risk of incident end-stage kidney disease (ESKD) independently of such established risk factors as lower baseline–estimated glomerular filtration rate (eGFR) [21,34–37]. Increased plasma FGF23—a marker of phosphorus overload—has also been shown to be a robust risk factor for kidney disease progression in CKD patients, as depicted in Fig. 17.1 showing the direct association between FGF23 and CKD progression in individuals with advanced CKD [17,18,24,59]. Even among individuals with normal kidney function and serum phosphorus concentrations within the normal range, a higher serum phosphorus level at baseline was independently associated with higher risk of incident CKD [35]. This suggests that excess serum phosphorus may impair renal health at all levels of kidney function.

Observational studies examining the relationship between dietary phosphorus consumption, and kidney disease progression are much fewer in number, in large part because of limitations in estimating phosphorus consumption using standard dietary instruments. Nonetheless, to try to overcome this limitation, several studies used urinary phosphorus excretion as a proxy for dietary phosphorus consumption. In an

**FIGURE 17.1** Hazard ratio (95% CI) for the progression of kidney disease as indicated by the initiation of chronic hemodialysis in patients with advanced chronic kidney disease according to quartiles of fibroblast growth factor 23 at baseline. Model 1 was adjusted for age, gender, and race. Model 2 was adjusted for variables in Model 1 plus smoking, alcohol intake, diabetes, hypertension, prevalent cardiovascular disease, Charlson score, body mass index, systolic and diastolic blood pressure, homocysteine, folate, vitamin B<sub>12</sub>, treatment arm, hemoglobin, estimated glomerular filtration rate, albumin, calcium, phosphorus, 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D, intact parathyroid hormone, total cholesterol, LDL-cholesterol, HDL-cholesterol, and triglycerides. Model 3 adjusted for variables in Model 2 plus medications. Quartile 1 is the referent group in all models. *CI*, Confidence interval; *HDL*, high-density lipoprotein; *LDL*, low-density lipoprotein. From Kendrick J, Cheung AK, Kaufman JS et al. FGF-23 associates with death, cardiovascular events, and initiation of chronic dialysis. *J Am Soc Nephrol* 2011;22:1913–22.

analysis of 795 participants of the modified diet in renal disease study, Selamet et al. found no statistically significant associations of urinary phosphorus excretion (from 24-hour urine collections at baseline) with the development of ESKD over an average of 16 years of follow-up [68]. In a retrospective cohort study of 175 Japanese CKD patients who were hospitalized and placed on a low-protein diet, higher 24-hour urinary phosphorus/creatinine clearance ratios at baseline were associated with higher risk of CKD progression (i.e., the development of a 50% decline in eGFR or ESKD) independently of other risk factors over about 1.5 years of follow-up [69]. However, 24-hour urine collections in this latter study were obtained while patients were hospitalized and after they were placed on a low-protein diet. So the urine measurements most likely did not reflect ambient dietary phosphorus consumption at home after discharge. Furthermore, a study of CKD patients who underwent detailed balance studies to examine the effects of calcium-based phosphorus binders on total-body phosphorus balance showed that urinary phosphorus excretion was more closely associated with total-body phosphorus retention than dietary phosphorus consumption, indicating

that 24-hour urinary phosphorus excretion may not be a good proxy for dietary phosphorus consumption in CKD patients [70]. In aggregate the balance of data from observational studies does not demonstrate a clear association of dietary phosphorus intake with CKD progression.

There are few prospective trials testing whether reducing dietary phosphorus attenuates CKD progression, and the results remain unclear. Nevertheless, a number of studies have shown that dietary protein restriction may help slow kidney disease progression in CKD patients, as reviewed elsewhere in this text. Since dietary phosphorus is closely linked to protein intake, it is possible that concomitant reductions in phosphorus intake may have contributed to the beneficial effect of protein restriction. Several small human studies support this possibility. Maschio et al. showed that the progression of kidney disease (as assessed by increases in the reciprocal of serum creatinine) was significantly slower in three groups of patients assigned to low-phosphorus diets (600–750 mg/day) (total  $n = 53$ ) than in a fourth group of patients ( $n = 30$ ) consuming an unrestricted diet estimated to provide 900 mg of phosphorus per day [32,71]. Interestingly, the magnitude of change in the reciprocal of serum creatinine with phosphorus restriction in this study was inversely related to baseline kidney function [32], suggesting that dietary phosphorus restriction is most beneficial when implemented in early CKD. In a study of 39 CKD patients, Barsotti et al. showed that reducing phosphorus intake (to 7 mg/kg/day) in CKD patients already consuming low-nitrogen (protein) diets was more effective in preserving kidney function than consuming a low-nitrogen diet with higher amounts of phosphorus (12 mg/kg/day) over about 1 year of follow-up [20]. In a subsequent study by the same group, 55 patients with moderate CKD (mean creatinine clearance, 30 mL/min) were followed on ad libitum diets for about 12 months after which they were assigned to a low-phosphorus (6.5 mg/kg/day), low-nitrogen diet for an average of 21 months ( $n = 29$ ), or a conventional low-nitrogen diet providing 12 mg phosphorus/kg/day of phosphorus per day for about 17 months ( $n = 26$ ) [19]. Creatinine clearance rates in both groups were noted to decline at an equal rate while the patients were consuming ad libitum diets. The creatinine clearance stabilized in the group assigned to the low-phosphorus, low-nitrogen diet, whereas it continued to decline in the conventional low-nitrogen diet group. The authors interpreted these data to suggest that a low-phosphorus diet confers a benefit on kidney disease progression above and beyond low protein intake in patients with moderate CKD.

While intriguing, these studies have a number of critical limitations that should merit caution when interpreting the results. First, they did not consistently isolate the effects of phosphorus restriction from the potential beneficial effects of other interventions, such as protein restriction and/or more intensive medical care due to frequent study visits. This makes it unclear whether dietary phosphorus restriction per se was the primary beneficial intervention [30]. In addition, the number of patients studied was very small; the intervention periods were relatively short; contemporaneous, well-matched controls were not used; and changes in serum creatinine or creatinine clearance over time were not corrected for any changes in muscle mass owing to decreased protein intake. Furthermore, not all studies report beneficial effects of dietary phosphorus restriction, and two small studies showed no effect of phosphorus restriction on kidney disease progression in CKD patients [72,73].

Due to these limitations, at present there is no good-quality evidence in humans that supports the use of dietary phosphorus restriction to preserve kidney function in CKD patients. Randomized controlled trials formally testing whether dietary phosphorus restriction attenuates kidney disease progression in predialysis CKD patients are now needed, particularly in light of the encouraging animal and human data reviewed earlier.

### **Dietary phosphorus restriction in CKD: practical considerations moving forward**

Despite the lack of randomized controlled trials supporting its efficacy, restricting dietary phosphorus intake has been advocated for the management of disturbances in bone and mineral metabolism in CKD since the 1970s [57,74]. These recommendations were based upon animal and human studies showing that even modest reductions in phosphorus intake lowered PTH concentrations, attenuated parathyroid gland hyperplasia, and ameliorated high-turnover bone disease, particularly in early CKD [47–49,51,56,75]. More recently, therapy with noncalcium-based oral phosphorus binders and consumption of vegetable sources of phosphorus with low bioavailability were shown to decrease plasma FGF23 concentrations in CKD patients [50,53–55], further supporting the utility of restricting dietary phosphorus absorption in CKD. To date, however, the utilization of dietary phosphorus restriction in clinical practice has been limited by a number of practical issues, many of which will need to be addressed in the design of any future clinical trials assessing the efficacy of phosphorus restriction in slowing CKD progression.

First, the optimal timing of dietary phosphorus restriction in CKD patients needs to be more clearly defined. Current clinical practice guidelines are available from the National Kidney Foundation Kidney Disease Outcome Quality Initiative (KDOQI) and the Kidney Disease Improving Global Outcomes (KDIGO) Study Group [76,77]. Both sets of guidelines essentially advocate prescribing dietary phosphorus restriction to avoid biochemical evidence of phosphorus overload, defined either as hyperphosphatemia or elevations of PTH above stage-specific threshold levels. The guidelines contain subtle differences as to when to initiate therapy. The KDOQI guidelines recommend adjusting dietary phosphorus intake to maintain serum phosphorus concentrations within the normal range. In contrast the KDIGO guidelines do not support initiating therapy until serum phosphorus concentrations are frankly elevated, discouraging intervention in individuals with normal serum phosphorus concentrations. This latter approach is perhaps reasonable given the lack of clinical trial data showing that lowering dietary phosphorus absorption (either through lower phosphorus intake or the use of oral phosphorus binders) improves clinical outcomes. However, waiting for the evidence of phosphorus overload to manifest prior to instituting dietary phosphorus limitation may miss an important opportunity to ameliorate kidney injury in early CKD. Indeed, studies showed that rats with experimentally induced kidney disease fed with high-phosphorus diets developed extensive renal parenchymal damage even in the absence of significant increases in serum phosphorus [26,67]. Furthermore, CKD patients prescribed low-phosphorus diets—manifested stabilization of kidney function even though their serum phosphorus concentrations were well within the normal range throughout the study period [19,32]. While these data suggest that implementing dietary phosphorus restriction in mild-to-moderate stages of CKD may help to protect residual renal function, even in the absence of overt evidence of phosphorus excess, it is unclear exactly how early during the course of kidney disease dietary phosphorus restriction should be implemented to maximize these potential benefits. This will require further study.

Further complicating this issue is the lack of evidenced-based recommendations for the degree of dietary phosphorus restriction that should be prescribed in individual patients. Although older KDOQI guidelines suggest phosphorus restriction to 800–1000 mg/day in stage 3–5 CKD patients with hyperphosphatemia or elevated PTH levels, there exist few data to support this recommendation. Further, it seems unlikely that one target range would be suitable for such a wide spectrum of kidney disease severity. Indeed, animal studies have shown that as renal function is reduced, the nephrotoxicity of excess

phosphorus is greatly enhanced [26,27], so that progressively smaller quantities of phosphorus intake are needed to induce kidney injury at lower levels of kidney function. Consistent with this finding, reductions in phosphorus intake that were proportional to concurrent reductions in glomerular filtration rate were shown to be necessary for maintaining normal serum phosphorus and PTH concentrations in canine models of CKD [56]. Whether similar CKD stage-specific, proportional decreases in phosphorus intake are more appropriate for the treatment of disorders of mineral metabolism and preservation of kidney function than a single target range has not been well studied in humans and remains unclear. Addressing this issue will be critical for developing rational recommendations for dietary phosphorus restriction in patients across the spectrum of kidney disease.

In addition, appropriate targets for gauging the efficacy of therapy are needed. While serum phosphorus concentrations would seem to be natural candidates, population-based data showed that even small decreases in serum phosphorus ( $\sim 0.3$ – $1.0$  mg/dL) within the normal range were associated with decreased risks of adverse outcomes, including cardiovascular disease, progression of kidney disease, and death [4–6,35,36,78]. Targeting such small changes in serum phosphorus to gauge the efficacy of phosphorus reduction strategies in individual predialysis CKD patients would be unrealistic in a clinical trial, much less in clinical practice. This is especially the case given the wide daily fluctuations in serum phosphorus concentrations due to natural postprandial or diurnal variation [79]. Further, studies in CKD patients have shown that serum phosphorus concentrations are minimally responsive to decreases in dietary phosphorus absorption unless intake is severely restricted. FGF23 has been proposed as a more appropriate biomarker to gauge the efficacy of phosphorus reduction strategies given that plasma FGF23 concentrations manifest much less random variation [80]. In support of this, modest restrictions in dietary phosphorus consumption produce measurable decreases in FGF23 and PTH, suggesting that these markers may be better integrated ones of phosphorus responsiveness. In addition, since elevations in plasma FGF23 are among the earliest manifestations of disordered phosphorus metabolism in CKD [81], FGF23 could also potentially serve as a biomarker to help identify early-stage CKD patients with normal serum phosphorus and PTH levels who may nevertheless benefit from dietary phosphorus restriction in order to maintain phosphorus balance. Future studies will need to test this possibility and determine the most appropriate targets for assessing the efficacy of phosphorus restriction in individual patients.

Finally, given the close relationship between dietary phosphorus and protein, reasonable concerns have been raised that restricting phosphorus intake would require a reciprocal restriction in protein intake that could exacerbate protein-energy wasting in advanced CKD [82]. As such, practical strategies for safely restricting phosphorus intake in the outpatient setting need to be better defined. Importantly, numerous strategies have already been proposed, with most involving a shift in the focus of dietary phosphorus management from globally reducing phosphorus (and thus, protein) intake to optimizing the types and sources of phosphorus being consumed [83]. Such strategies include decreasing the consumption of processed foods containing high quantities of phosphorus-based food additives, consuming more vegetable-based protein sources with lower phosphorus bioavailability, or increasing the consumption of foods with low phosphorus-to-protein ratios [83]. Before dietary phosphorus restriction can be broadly adopted in the management of patients with predialysis CKD, these and the other barriers reviewed earlier will need to be addressed.

## Conclusion

Disorders of phosphorus metabolism are strongly linked to adverse CKD outcomes, including CKD progression. Given the central role of dietary phosphorus intake in the pathogenesis of disturbances of phosphorus homeostasis in CKD, restriction of dietary phosphorus consumption may represent an effective intervention for mitigating the decline of kidney function in CKD patients. While the balance of experimental and human data supports this thesis, the lack of randomized, controlled trials examining the utility and/or feasibility of this intervention precludes the ability to recommend dietary phosphorus restriction for the attenuation of CKD progression at this time. As the phosphorus content of westernized diets will only increase in the future, initiating these trials should be a high priority, with the long-term goal of determining whether dietary phosphorus intake may be an effective and safe therapy for slowing the progression of CKD.

## Introduction: Gut-derived uremic toxins

Numerous uremic retention solutes (URS) that would normally be cleared by the kidneys accumulate in chronic kidney disease (CKD). These solutes are called uremic toxins when they interact negatively with biological functions. Many studies have shed light on the URS production mechanisms, and a classification of URS has been proposed according to their origin: (1) endogenous metabolism; (2) intestinal microbial metabolism, and (3) exogenous intake.

Studies with axenic mice or CKD patients undergoing a colectomy have helped to characterize the origin of URS [1,2]. In particular, using a spectrometry-based approach in these models, 11 major URS were identified as being microbiota-derived uremic solutes, including tryptophan (TRP) metabolites such as indoxyl sulfate (IS) and indole-3-acetic acid (IAA). IS and IAA have been almost consistently associated with increased mortality in CKD patients [3–7]. TRP metabolites, notably IS and IAA, are the most representative gut-derived uremic toxins and have emerged as an important therapeutic target.

## Metabolism of tryptophan and indole production

TRP is an essential amino acid only supplied by dietary proteins composed of a  $\beta$ -carbon connected to the 3-position in an indole group (Fig. 18.1). Dietary TRP is

metabolized via three pathways in the gastrointestinal tract, leading to kynurenine (KYN), indole, and serotonin derivatives [8].

The KYN pathway is the main metabolic route (95%) of TRP catabolism and is mediated by the enzymes tryptophan 2,3-dioxygenase and indoleamine 2,3-dioxygenase (IDO) in both immune and epithelial cells in the intestinal tract. Various metabolites can derive from the KYN pathway: 3-hydroxyanthranilic acid, 3-hydroxykynurenine (3-HKYN), kynurenic acid (KYNA), anthranilic acid, and quinolinic acid. The KYN pathway is well-balanced under physiological conditions but upregulated in several chronic diseases such as cancer and neurodegenerative disorders [9]. The accumulation of KYN metabolites has been less studied during CKD. Their plasma levels do not rise proportionally to the reduction in renal function because KYN is not a metabolic end product that is normally excreted by the kidney [10]. KYN levels seem increased in CKD patients [11] but this was not confirmed in all studies [12]. The mechanisms that explain a high level of KYN in CKD is not clear. IDO activity increases with the CKD severity and some data suggest that the induction of IDO may be a consequence of chronic inflammation [13]. Alternatively, renal insufficiency could impair the conversion of KYN to one of its downstream metabolites but this mechanism is unclear [10].

The gut microbial fermentation of dietary TRP is the main source of indole production. Indole is directly formed by intestinal bacteria expressing tryptophanase (e.g., *Lactobacillus*, *Bifidobacterium longum*, *Bacteroides*

FIGURE 18.1 Overview of different pathways of tryptophan metabolites generation in human gut and endogenous production. 5-HT, 5-Hydroxytryptamine; ArAT, aromatic amino acid aminotransferase; CYP2E1, p450 cytochrome CYP2E1 enzyme; I3A, indole-3-aldehyde; IAA, indole-3-acetic acid; IAAld, indole-3-acetaldehyde; IAM, indole-3-acetamide; IDO, indoleamine 2,3-dioxygenase; IPA, indole-3-propionic acid; KMO, kynurenine-3-mono-oxygenase; SULT, sulfatase; TDO, tryptophan 2,3-dioxygenase; TMO, tryptophan monooxygenase; TNA, tryptophanase; Tph1, tryptophan hydroxylase 1; TrD, Tryptophan decarboxylase; TRP, tryptophan.

*fragilis*, *Parabacteroides distasonis*, *Clostridium bartlettii*, and *Eubacterium hallii*) [14]. Bacteria like *Lactobacillus* spp. convert TRP into IAA and indole-3-aldehyde through the tryptophan monooxygenase (TMO) [15]. IAA can also be produced endogenously via tryptamine catabolism by the tryptophan decarboxylase [16]. Bacteria like *Clostridium sporogenes* convert TRP into indole-3-propionic acid (IPA) via aromatic amino acid aminotransferase. After absorption from the intestinal tract into portal circulation, indole is first oxidized by the microsomal p450 cytochrome CYP2E1 enzyme and then converted into IS via the sulfatase enzyme (SULT1A1). Therefore, in CKD patients the gut microbial imbalance, called dysbiosis, is associated with an increased toxic metabolites generation, such as IS and IAA [17].

Under the catalytic action of tryptophan hydroxylase (Tph), TRP is degraded into 5-hydroxytryptamine (5-HT, called serotonin). Tph2 is expressed in neuronal cells. Tph1 catalyzes peripheral serotonin synthesis and is mainly expressed in the enterochromaffin cells of the gut. These cells are responsible for almost 90% of peripheral 5-HT synthesis. Additionally, a small amount of serotonin is synthesized in bone tissues. Several other metabolites are derived from this pathway such as 5-methoxytryptophan (5-MTP), 5-HIAA (5-hydroxyindoleacetic acid) or melatonin. Serum 5-HT and 5-HIAA increase during CKD whereas 5-MTP

seems to decrease. So far, these metabolic changes have been poorly studied in CKD [18,19].

### Tryptophan metabolites as aryl hydrocarbon receptor ligands

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor receptor and was discovered as a mediator of the toxic responses of halogenated and polycyclic aromatic hydrocarbons, such as dioxin (Fig. 18.2). Nevertheless, evidence accrued in the past years has shown that AhR is not only a receptor for xenobiotics but it can be activated by several endogenous ligands like TRP metabolites [20,21]. In CKD context, using microarray analyses of human umbilical vein endothelial cells (HUVECs), it has been shown that IS and IAA lead to an increased expression of AhR-induced genes [21]. The AhR is located in the cytoplasm of cells inside multiprotein complex (formed with stabilizer proteins, like heat shock protein 90, cochaperon p23 (P23), and X-associated protein 2. After ligand binding, AhR is activated by a conformational change that allows its translocation to the nucleus. After its phosphorylation by protein kinase C, the ligand-bound AhR complex is translocated into the nucleus. This ligand-bound AhR releases the multiprotein complex that binds to the AhR nuclear translocator

FIGURE 18.2 Mechanism of AhR activation by tryptophan-derived uremic toxins. *AhR*, Aryl hydrocarbon receptor; *ARNT*, AhR nuclear translocator; *HSP90*, heat shock protein 90; *OAT*, organic anion transporter; *XAP2*, X-associated protein 2.

(ARNT) through its PAS domain, resulting in the ligand-bound AhR-ARNT dimer. This dimer binds to specific DNA sequences (referred to as DRE or XRE for dioxin- or xenobiotic-responsive element) present in the promoter of wide genes, including cytochrome P450, family 1 member 1A (*Cyp1A1*); cytochrome P450, family 1, subfamily B (*Cyp1B1*); AhR repressor; and cyclooxygenase-2 (*COX-2*) [22].

The activation of AhR is first known to mediate the expression of drug metabolism enzymes but is also involved in diverse physiological functions such as the regulation of T-cell differentiation, conception and embryonic/fetal development, mediation of stress, and inflammation responses [23]. Although indoles and AhR activation in general appear to be beneficial, a large accumulation of TRP metabolites in CKD is associated with poor outcomes [3–7].

The classic AhR signaling is not able to explain all roles attributed to AhR. Thus a nongenomic inflammatory pathway of AhR activation may also be involved. The activation of transcription factors such as nuclear factor  $\kappa$ B (NF- $\kappa$ B; which promotes the inflammatory response) and activator protein 1 (AP-1; which regulates target genes involved in cellular proliferation, transformation, and cell death functions) has also been described. The interaction between AhR and NF- $\kappa$ B can lead to activation or mutual transrepression of their activities, depending on the duration, the cell type used, and the promoter being assayed [24]. The cytosolic AhR can activate other cytosolic proteins, including proteins of the mitogen-activated protein kinase (MAPK) family, extracellular signal-regulated kinase (ERK), p38, and Jun-NH2-terminal kinase (JNK) [16]. MAPKs phosphorylate

downstream transcription factors and thereby alter gene expression to direct a specific cellular response. These pathways were described in carcinogenesis processes, and their relevance in CKD complications has still to be demonstrated.

### Tryptophan metabolites promote CKD progression

Several studies have demonstrated that TRP metabolic products are involved in CKD progression (Fig. 18.3) [25–27].

First, IS accelerates fibrosis by increasing the expression of transforming growth factor-beta, tissue inhibitor of metalloproteinase-1, intercellular adhesion molecule (ICAM-1 or CD-54), and procollagen I in cultured tubular cells [28–30]. In a porcine proximal tubular cell model, IAA reduced viable cell number, mainly through the induction of apoptosis. However, in this observation, IAA concentration was higher than that observed in CKD patients [31]. In cultured human renal tubular cells, IS reduced Klotho kidney expression through aberrant DNA methylation at the 5-position of cytosine in CpG dinucleotides in the Klotho gene [32]. This is of interest since a decrease in Klotho expression has been reportedly associated with kidney fibrosis. IS increased DNA methyltransferases 1, 3a, and 3b expression that are the key enzymes for the regulation of DNA methylation [32]. This suggests that epigenetic modifications by URS of specific genes may be an important pathophysiological mechanism for CKD progression [32].

**FIGURE 18.3** Mechanisms involved in nephrotoxicity of tryptophan-derived uremic toxins. *AhR*, Aryl hydrocarbon receptor; *CKD*, chronic kidney disease; *EGFR*, epidermal growth factor receptor; *IAA*, indole-3-acetic acid; *ICAM*, intercellular adhesion molecule; *IL-6*, interleukin 6; *IS*, indoxyl sulfate; *MCP-1*, monocyte chemoattractant protein 1; *MMP 2/9*, matrix metalloproteinases 2/9; *NF-κB*, nuclear factor κB; *OAT*, organic anion transporter; *RAAS*, renin–angiotensin–aldosterone system; *ROS*, reactive oxygen species; *TGF-β*, transforming growth factor-beta; *TIMP-1*, tissue inhibitor of metalloproteinase-1.

Second, IS accumulation in tubular cells lowers their antioxidative capacity [33,34] and increases the production of reactive oxygen species (ROS) [35]. IS is able to downregulate the renal expression of factor 2–related erythroid nuclear factor 2 (Nrf2) through the activation of NF-κB in human proximal tubular cells. Nrf2 controls antioxidant and antiinflammatory cellular responses by upregulating heme oxygenase-1 and NAD(P) H:quinone oxidoreductase 1 (NQO1). Also, IS inappropriately activated the renin–angiotensin–aldosterone system (RAAS) in proximal tubular cells, promoting kidney damage [36].

Third, IS markedly stimulates inflammation in tubular cells. Indeed, cultured mouse proximal renal tubular cells treated with IS increased their production of major proinflammatory cytokines such as interleukin 6 (IL-6) [27]. IS also injured podocytes by perturbing the actin cytoskeleton, decreasing the expression of podocyte-specific genes, and modulating the inflammatory response in cell culture [37].

The impact of IS on renal disease progression has been confirmed in virtually all animal studies. In CKD rats, the administration of IS accelerated glomerular sclerosis, fibrosis, and CKD progression [26,33,38]. IS

administration in mice increased albuminuria by altering podocyte structure [37]. Decreasing IS accumulation in CKD rats by using the oral adsorbent AST-120 decreased tubular epithelial-to-mesenchymal transition [25]. In CKD rats, the oral intake of IAA at concentrations found in CKD patients resulted in a higher excretion of *N*-acetyl-β-glucosaminidase—a marker of tubular injury, an alteration of renal function, and a higher glomerular sclerosis index [39]. These findings are however not unanimous since in a recent study in CKD rats, administration of IS did not worsen renal impairment, and fibrosis and nonsignificant differences in *Klotho* mRNA expression were observed [40]. In a prospective CKD patients cohort, baseline IS was correlated with renal progression [41]. Further studies are therefore needed to explain these discrepancies.

On the contrary, on other intestinal TRP metabolites, IPA may be a renal protector against the development of CKD [42]. The putative protective effect of serum IPA may be explained by its antioxidative stress capacity, as IPA is a potent scavenger of hydroxyl radical [43].

The impact of kynurenine (KYN) metabolites on renal function has been less explored. KYN affects mesangial cell proliferation in culture [44]. More direct

evidence for the effects of KYN metabolites on the progression of kidney disease has been revealed by studies using kynurenine-3-mono-oxygenase (KMO)-deficient mice, which catalyzes the hydroxylation of KYN to form 3-HKYN. Plasma levels of KYN and KYNA are higher in KMO<sup>-/-</sup> mice and a higher albuminuria and mild podocyte foot process effacement are observed [45].

Serotonin metabolites such as 5-MTP may have beneficial effect on renal function. 5-MTP attenuates the proinflammatory factor NF- $\kappa$ B and increases the anti-inflammatory and antioxidant transcription factor Nrf2. In addition, treatment with 5-MTP in CKD mice significantly attenuated the upregulation of profibrotic proteins like collagen I, fibronectin, and E-cadherin [18].

Whether activation of AhR also accounts for some adverse effects on tubular cells and podocytes is still unknown. At least several actions of IS on proximal tubular cells, such as dysregulation of RAAS, are mediated by AhR [46]. A number of studies on adult mouse and human kidney have shown that AhR is localized in podocytes nuclei, as well as in distal tubules in human kidney. After exposure to IS, nuclear translocation of AhR was observed in cultured mouse podocytes [37].

Finally, AhR epidermal growth factor receptor (EGFR) activation by IS could contribute to renal tissue remodeling. Treatment of mice with IS significantly activated the renal EGFR and increased the tubulointerstitial expression of profibrotic proteins such as matrix metalloproteinases 2 and 9 [47]. The interaction between indole and EGFR needs to be confirmed.

### **Role of organic anion transporters in the nephrotoxicity of tryptophan metabolites**

IS and IAA are secreted into the renal proximal tubule lumen by organic anion transporters (OATs) [48]. After IS exposure in rats, immunohistochemistry located IS in proximal and distal tubules, which express OAT1 (proximal tubules) and/or OAT3 (proximal and distal tubules) [33]. OAT1-knockout mice showed dramatically higher plasma concentrations of IS [49] and administration of the OAT inhibitor probenecid reduced IS toxicity in proximal tubular cells [33]. IAA is excreted in urine by tubular secretion through the OAT1 transporter [50]. Another tubular transporter, ATP-binding cassette transporter subfamily G member 2, has also been recently identified as an IS/IAA transporter [51].

Because several studies have suggested that the accumulation of TRP-metabolites accelerates tubular cell injury and acts as nephrotoxins, the preservation of renal residual function (RRF) is important. Different cohorts of hemodialysis patients have observed that

plasma IS concentration is higher in anuric patients as compared with patients with conserved diuresis [52]. This gives some evidence that a reduction in TRP metabolites by RRF may be responsible for the benefits of observed association between RRF and mortality.

## **Tryptophan metabolites induce a vascular procoagulant phenotype and cardiovascular complications**

### **Procoagulation state**

CKD is associated with increased risk for thrombotic events (Fig. 18.4). Treatment of vascular smooth muscle cells (VSMCs) and peripheral blood mononuclear cells by IS or IAA at disease-relevant concentration increased their thrombogenicity. IS/IAA and KYN are able to upregulate tissue factor (TF) level by the AhR pathway, a major protein involved in the initiation of the coagulation process [53,54]. IS/IAA increased the stability of TF by inhibiting its ubiquitination [21,55]. Some studies suggest that IS promotes thrombosis with the ability to induce phosphatidylserine (PS) exposure and microparticles (MPs) release by red blood cells [56]. Externalized PS and MPs are binding sites for factor Xa and prothrombinase complexes. IS prompts to a ROS-induced p38MAPK signaling in platelets, triggering platelet hyperactivity that plays a crucial role in the uremic procoagulation state [57].

In good concordance, in mice exposed to IS, the weight of thrombus after laser-induced endothelial injury is increased [58]. Also, KYN enhances clotting after vascular injury in mice and regulates thrombosis in an AhR-dependent manner [54].

These experimental data have been confirmed in different cohorts of CKD patients. The concentration of circulating TF is positively correlated with plasma levels of IS and IAA [21]. KYN has been associated with serum markers of hypercoagulation in chronic dialysis patients [59]. Accumulations of IS, IAA, and KYN are independently associated with an increase of arteriovenous fistula thrombosis [54,60].

### **Inflammation state, oxidative stress, and endothelial dysfunction**

Chronic inflammation and oxidative stress are key mechanisms during endothelial dysfunction and atherosclerosis. The correlation between IS/IAA accumulation and inflammatory markers such as monocyte chemoattractant protein 1 or IL-6 has been confirmed in clinical studies in CKD patients [61].

In HUVECs, IS induced a decrease in endothelial proliferation and wound repair [62]. IS administration

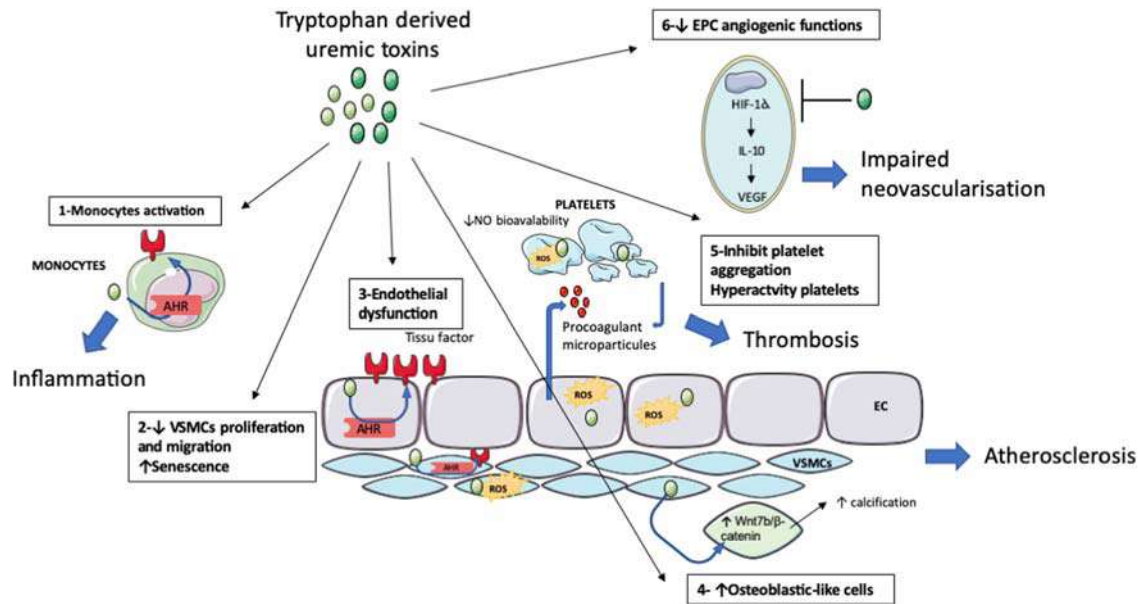

FIGURE 18.4 Schematic effect of tryptophan-derived uremic toxins in cardiovascular system. *AhR*, Aryl hydrocarbon receptor; *EC*, endothelial cell; *EPC*, endothelial progenitor cells; *HIF-1 $\alpha$* , hypoxia-inducible factor-1 $\alpha$ ; *IL-10*, interleukin 10; *NO*, nitric oxide; *ROS*, reactive oxygen species; *VSMCs*, vascular smooth muscle cells; *VEGF*, vascular endothelial growth factor.

increased the expression of adhesion molecules such as ICAM-1 and E-selectin, which are involved in the pathophysiology and progression of atherosclerosis [63]. In HUVECs and human aortic smooth muscle cells, IS-induced IL-6 expression and ROS production are related to the activation of AhR through the activation of p65 (subunit of NF- $\kappa$ B) signaling transduction [64,65]. In HUVECs IAA triggered an inflammatory nongenomic AhR/p38MAPK/NF- $\kappa$ B pathway leading to the pro-inflammatory COX-2 upregulation that induced endothelial inflammation and oxidative stress [7]. Similarly, as observed in HUVECs, cardiomyocytes treated with IS showed an increased expression of cardiac hypertrophy- and fibrosis-related molecules through the activation of NF- $\kappa$ B and MAPKs pathways.

Acute exposure to IS induced the proliferation of VSMCs [66]. The proliferative effect of IS has been attributed to the subsequent activation of different pathways, including MAPKs [36], AhR/NF- $\kappa$ B [67], and prorenin [68]. In contrast, chronic exposure to IS decreased VSMCs proliferation. These antiproliferative properties have been associated with elevated NADPH oxidase-dependent production of ROS [36] and upregulation of the cell cycle inhibitors p21 and p27 [69]. Long-term IS exposure also promoted VSMCs senescence [70]. Therefore the low level of VSMCs proliferation associated with long-term IS exposure might reflect a state of replicative senescence that follows the increase in proliferation associated with acute IS exposure.

In CKD mice, IS was shown to impair neovascularization in ischemic hindlimbs, while lowering serum IS

levels using AST-120 could improve this condition [71]. Endothelial progenitor cells (EPCs) are pivotal in neovascularization. IS decreased the proangiogenic functions of EPCs by suppressing hypoxia-inducible factor-1 $\alpha$  activation and consecutively the expression of IL-10 and vascular endothelial growth factor synthesis, known to be essential for EPCs mobilization and angiogenesis [71].

### Vascular calcification

Vascular calcification is an independent risk factor for the development of cardiovascular (CV) diseases. In CKD patients, serum IS levels were independently correlated with aortic calcification suggesting that IS may act as a pro-calcifying toxin [3]. IS not only increases oxidative stress [72], but also the expression of bone-related proteins [73,74]. IS enhanced the transformation of aortic VSMCs into osteoblastic-like cells by activating Wnt7b/ $\beta$ -catenin expression [74]. IS increased inorganic phosphate-induced VSMCs calcification and osteogenic transdifferentiation. IS induced methylation and subsequent transcriptional suppression of the  $\alpha$ -Klotho gene, which promoted vascular calcification in VSMCs cultures and in 5/6-nephrectomized rats [73]. IS suppressed the expression of fetuin-A via AhR signaling in human hepatoma HepG2 cells. Fetuin-A is a liver-derived circulating protein that has a potent calcification-inhibitory activity [75].

In a rat model, an IS exposure at serum levels similar to those experienced by hemodialysis patients

significantly increased calcification in the aorta and peripheral arteries [40]. In this study, using a proteomic approach, an association between calcification events, coagulation, and glucometabolic signaling pathways was shown. Additional metabolic linkage to these pathways revealed that IS exposure engendered an insulin resistant state. Short-term exposure to IS before calcification had been established showed an activation of inflammation and coagulation signaling pathways in the aorta, demonstrating that these signaling pathways are causally implicated in IS-induced arterial calcification [40].

### **Tryptophan metabolites and cardiovascular events in CKD patients**

High serum IS levels are associated with increased CV events [3] and patients with a history of CV diseases have higher serum IS concentrations than those without CV events [3]. Similarly, CKD patients with high serum IS levels presented a higher incidence of first heart failure event [6] and peripheral artery disease [76]. Serum IS level has been associated with the severity of coronary artery disease [77] and is an independent predictor for coronary restenosis in patients receiving drug-eluting stent-implantations [78]. A higher serum IS levels was significantly associated with an increased prevalence of diastolic dysfunction, despite preserved kidney function [79]. Another study revealed that, independent of kidney function, serum IS levels were significantly associated with CV events in patients with dilated cardiomyopathy [80]. Similarly, the accumulation of plasmatic IAA predicted CV diseases in CKD patients [7]. However, some studies suggested that IS/IAA were not associated with CV outcomes in hemodialysis patients [81,82]. These discrepant findings can be explained by a number of factors. During maintenance dialysis, IS could contribute to morbid events by causing a loss of RRF in response to its renal toxicity [52]. Therefore the presence or absence of RRF can be a major confounder in observational studies. In the HEMO study [82], IS was not associated with global mortality but with sudden cardiac death in patients with lower serum albumin (<3.6 g/dL). This observation was confirmed in another cohort of patients undergoing percutaneous revascularization for coronary artery disease or peripheral artery disease [83]. Because more than 90% of IS is bound to albumin, a lower albumin level may allow a higher free concentration of IS, potentiating its value as a prognostic factor for CV diseases [83].

Some preliminary observations suggest that IS accumulation may play a role in the development of arrhythmogenesis in CKD patients through atrial

remodeling involving oxidative stress, inflammation, and profibrotic factors [84]. The depolarization of cardiomyocyte is significantly decreased after the administration of IS in animal models [85]. In good concordance, patients with corrected QT prolongation on the electrocardiogram had higher IS levels [85].

Similar associations have been found with the metabolites issued from the KYN pathway. 3-HKYN was higher in patients with CV disease [86] and was associated with an increase in early mortality in patients with a recent ischemic stroke independent from renal function [87]. In CKD patients, the TRP/KYN ratio was related to the carotid intima-media thickness, a presymptomatic predictor of atherosclerosis [88]. In CKD patients, a higher IDO activity was associated with a larger size of carotid plaques [89].

The hypothesis that AhR activation is involved in CV toxicity of TRP-derived uremic toxins has been confirmed recently. Sera from CKD patients displayed a strong AhR-activating potential (AhR-AP). AhR-AP was correlated with renal function and IS concentration. Survival analyses revealed that CV events were more frequent in CKD patients with an AhR-activating concentration above median [90].

### **Tryptophan metabolites involved in musculoskeletal disorders**

The majority of studies highlighted the fact that TRP catabolites (mostly IS) play an important role in worsening bone mechanical properties by changing bone chemical composition and this may result in low bone turnover—a dynamic bone disease (Fig. 18.5). In mouse primary osteoblast culture, IS suppressed the expression of osterix, osteocalcin, and bone morphogenetic protein 2 mRNA and inhibited the formation of mineralized bone nodules. Although the molecular mechanisms that underlie the inhibition of differentiation are unclear. One hypothesis is the increase of oxidative stress induced by uptake of IS probably via AhR activation [91]. Osteoclasts and osteoblasts express OAT3 that allows IS uptake. IS reduced parathyroid hormone (PTH)-stimulated intracellular cyclic adenosine monophosphate production and decreased PTH receptor expression in osteoblastic cells. In osteoclasts, IS decreased JNK and ERK-phosphorylation as well as AP-1 DNA binding activity, which results in an alteration of their differentiation and function [92]. IS suppressed mRNA expression of receptor activator of NF- $\kappa$ B ligand, which is a pivotal factor for osteoclast differentiation via the AhR signaling pathway and reduced bone-resorbing activity of osteoclasts [92,93].

In a uremic animal model study, IS was shown to directly impact on bone elastic properties [94]. IS

FIGURE 18.5 Impact of tryptophan-derived uremic toxins on bone metabolism. *Ahr*, Aryl hydrocarbon receptor; *BMP2*, bone morphogenetic protein 2; *cAMP*, cyclic adenosine monophosphate; *OAT*, organic anion transporter; *PTH*, parathyroid hormone; *RANKL*, receptor activator of nuclear factor- $\kappa$ B ligand; *ROS*, reactive oxygen species.

decreased bone formation-related parameters in parathyroidectomized rats while bone resorption-related parameters were unchanged [95]. A cross-sectional study in hemodialysis patients found that serum IS was negatively correlated with bone formation markers, such as bone-specific alkaline phosphatase activity, and being independent of intact PTH levels [96]. Sclerostin, which has antianabolic effects on bone formation by inhibiting the Wnt/ $\beta$ -catenin pathway, was related to IS levels [97]. Some preliminary data suggest that IS can repress miR-29b microRNA precursor that negatively regulates the Wnt/ $\beta$ -catenin signaling [74].

Finally, in CKD rats, peripheral serotonin (5-HT) and its metabolite (5-HIAA) were increased. Both 5-HT and 5-HIAA were inversely associated with bone stiffness. These results must be confirmed in human [98].

Sarcopenia is frequently observed during CKD and the accumulation of TRP metabolites could participate to this phenotype by altering biologic functions and proliferation of muscle cells. In C2C12 myotubes, IS treatment induced a reticulum endoplasmic stress by increasing eukaryotic initiation factor 2 alpha phosphorylation and unfolded protein response. IS reduced myoblast determination protein 1 (myoD) expression, a key transcription factor involved in myogenic differentiation [99]. IS was reported to induce inflammatory cytokine expression (IL-6) and increase markers of muscle atrophy

(myostatin and atrogen-1) [100]. IS-mediated myotube atrophy may happen through ROS-MAPKs [101,102]. IS induced mitochondrial dysfunction by decreasing the expression of the key mitochondrial protein peroxisome proliferator-activated receptor gamma coactivator 1-alpha. IS was able to trigger autophagy in addition to decreasing mitochondrial membrane potential [103]. IS decreased exercise capacity via the induction of muscle oxidative stress in CKD mice [102]. Furthermore, the administration of IS in mice was able to increase key atrogenes expression such as atrogen-1, which is involved in proteolysis and in a decreased muscle mass [100]. A significant inverse association between plasma IS levels and skeletal muscle mass was also observed in CKD patients [104].

### Therapeutic strategies to reduce tryptophan metabolites accumulation and production

TRP metabolites have a high affinity with albumin (90%–95% in the case of IS/IAA) that explains their limited removal by classical dialysis since the free fraction is only able to diffuse across the dialysis membrane. Moreover, the free fraction decreases during dialysis, further reducing the clearance efficacy [10]. Even with “high efficiency” membranes, the dialytic

clearance of protein bound-toxins is a very small fraction of the urea clearance [105]. Therefore innovative strategies to decrease the production of URS in hemodialyzed patients and patients not yet treated by dialysis are needed. Because the majority of TRP metabolites are produced by intestinal microbiota, strategies that could modulate microbiota composition appear to be an attractive idea. Nevertheless, the relations between features of the gut microbiota, uremic toxin production, and CKD progression have not been explored prospectively in human.

## AST-120

AST-120 is an oral carbon adsorbent consisting of porous carbon particles, of approximately 0.2–0.4 mm in diameter, nonsoluble in water. Using a mass spectrometry approach, it was observed that AST-120 can adsorb at least 6 negatively charged and 17 positively charged URS, including TRP metabolites [106,107] with few adverse effects besides some constipation, nausea, or vomiting.

Several animal studies have demonstrated a beneficial effect of AST-120 in reducing toxic effect of TRP metabolites. AST-120 reduced vascular calcification [108], urinary albumin excretion, prevented glomerular sclerosis [109], decreased bone resistance to PTH [110], and improved muscle function [102,103]. Besides the adsorption of indole, AST-120 may induce a beneficial gut environment and decrease gut microbial fermentation of dietary TRP to indole [111].

Preliminary clinical trials in Japan suggested that AST-120 was effective in slowing the progression of renal disease and improving uremic symptoms [112]. However, this was not confirmed in the multinational, randomized, double-blind, placebo-controlled evaluating prevention of progression in CKD (EPPIC)-1 and EPPIC-2 trial that included 2035 adults, since no significant differences were observed [113]. The negative results of this study can be partially explained by the following: (1) the evolution of CKD in study subjects was less severe than was predicted; (2) the condition for initial dialysis was not identical within countries; (3) the deterioration of CKD in subjects and indicators of the severity of CKD were not consistent; and (4) the subjects showed poor compliance. Subsequent analyses revealed a significant reduction in the incidence of dialysis initiation in patients from AST-120 groups who succeeded to reach a compliance of 80% or greater. AST-120 seemed to be efficient to prevent kidney deterioration in a subgroup of patients with elevated proteinuria in addition to RAAS blockers [114]. Further studies on AST-120 are needed before generalization of its use.

## Probiotics, prebiotics, and fecal microbiota transplantation

Probiotics are modified microorganisms expressing specific exogenous enzymes that are able to survive stomach acid and bile, to increase the colon concentration of symbionts, and confer a health benefit. Prebiotics are indigestible food additives that promote the selective growth of beneficial bacteria while limiting the proliferation of pathogenic bacteria.

Preliminary experimental strategies were very encouraging [17,115]. Most of these studies have demonstrated a decrease in TRP metabolites. First, small human studies were beneficial [116]. But later larger human trials have not been equally convincing. Table 18.1 summarizes randomized clinical studies reporting the use of prebiotics, probiotics, and symbiotics in CKD on tryptophan metabolites. In recent metaanalyses in CKD patients, no beneficial effects have been observed in favor of a reduction in IS production [117]. But the protocols were all relatively short in duration (less than 3 months), diverse compounds and doses of pre/probiotics, design and patient populations (CKD or dialysis patients). In hemodialysis patients, the baseline levels of toxins were higher, allowing for a more efficient effect to be observed. The galenic formula of probiotics seems important. Indeed, as compared with hemodialyzed patients receiving regular capsules, only those patients treated with gastroresistant seamless probiotic-containing capsules experienced a decrease in serum IS levels [116]. The failure of human studies testing probiotics alone could be explained by an unfavorable environment due to the whole-body urea, and hence, the colic fluid urea that may alter the symbiotic microbiota. Attempts to restore the desired microbiome by introducing favorable microorganisms without simultaneously improving the gut's biochemical milieu, for instance by using prebiotics, seem to be doomed to failure.

Fecal microbiota transplantation (FMT) may be an interesting option to modify gut microbiota. FMT has been associated with improved clinical outcomes, albeit only used in routine care for *Clostridium difficile* infection. However, so far there are no data on the use of FMT in CKD and specifically on URS production.

## Low-protein diet and low-tryptophan diet

Because URS production is the consequence of amino acid transformation, decreasing protein intake may be a strategy to reduce TRP metabolites. Indeed, the poorly understood beneficial effects of low-protein diet (LPD) may be partially explained through such a mechanism.

**TABLE 18.1** Randomized controlled human studies reporting the use of prebiotics, probiotics, and symbiotics in chronic kidney disease on tryptophan metabolites.

Reference	Treatment	Design	Results
Lopes et al. [118]	Symbiotic: 40 g of extruded sorghum plus 100 mL of unfermented probiotic milk	Single-center, double-blind, placebo-controlled <i>n</i> = 58, HD; 7 weeks	↓ IS
Esgalhado et al. [119]	Resistant starch, 16 g/d	Single-center, double-blind, placebo-controlled <i>n</i> = 31, HD; 4 weeks	↓ IS
Borges et al. [120]	Probiotic: <i>Streptococcus thermophilus</i> , <i>Lactobacillus acidophilus</i> , <i>Bifidobacterium longum</i> , 90 billion colony-forming units per day	Single-center, double-blind, placebo-controlled <i>n</i> = 46, HD; 3 months	No effect on IS
Ramos et al. [121]	FOS, 12 g/d	Single-center, double-blind, placebo-controlled, randomized, crossover <i>n</i> = 50, eGFR between <45 mL/min/1.73 m <sup>2</sup> ; 3 months	No effect on IS, IAA
Elamin et al. [122]	Gum arabic, 10–40 g/d	Single-center, open-label phase, randomized, <i>n</i> = 36, Stage 3B-4; 4 weeks	No effect on IS
Rossi et al. [123]	Symbiotic: <i>Lactobacillus</i> , <i>Bifidobacteria</i> , and <i>Streptococcus</i> genera + prebiotic (inulin, fructo-oligosaccharides, and galacto-oligosaccharides)	Single-center, double-blind, placebo-controlled, randomized crossover trial <i>n</i> = 37; CKD stages 4–5; 6 weeks	↓ IS
Poesen et al. [124]	AXOS, 10 g twice daily	Single-center, double-blind, placebo-controlled, randomized, crossover <i>n</i> = 40, eGFR between 15 and 45 mL/min/1.73 m <sup>2</sup> ; 4 weeks	No effect on IS
Sirich et al. [125]	High-amylose corn starch (Hi-maize 260) 15 g/d	Single-center, double-blind, placebo-controlled <i>n</i> = 40, HD; 6 weeks	↓ IS
Meijers et al. [126]	Oligofructose-enriched inulin (ORAFIT Synergy 1, Tienen, Belgium) 10 g twice daily	Single center, nonrandomized, open-label phase <i>n</i> = 22, HD patients; 4 weeks	No effect on IS

AXOS, Arabinoxylan oligosaccharides; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; FOS, fructooligosaccharides; HD, hemodialysis; IAA, indole-3-acetic acid; IS, indoxyl sulfate.

High dietary proteins increase indole and IS production in healthy human [127]. LPD was efficient in reducing serum IS levels in CKD rats [128] and in hemodialysis patients [129]. However, it remains unclear if diet modulation could also affect the microbiota or if it is only the consequence of the reduction in protein intake. There are some preliminary data that observed a decrease in IS in mice fed with low-TRP diet [130]. However, in a small cohort of hemodialysis patients, no association between quantity of TRP intake and IS levels was observed [131]. Further studies are needed to confirm or infirm these preliminary results.

## Other directions

Manipulation of the gut microbial TRP catabolism using specific mutant bacteria may be interesting. Devlin et al. have identified an abundant family of microbial tryptophanases within the human gut and demonstrated that altering the abundance of bacteria harboring tryptophanase activity can serve as a means

of modulating IS production in gnotobiotic and conventional mice [132]. However, this strategy has not been explored in uremic conditions.

Besides microbiota modulation, decreased hepatic sulfation of indole and increased tubular secretion can represent new therapeutic targets. As indoxyl is sulfated in the liver, an inhibition of this pathway may be a novel therapeutic option. Rats with renal ischemia/reperfusion insult have been treated with phytochemical polyphenol compounds such as resveratrol or quercetin that show a potent inhibitory effect on SULT1A1. This strategy significantly inhibited hepatic production of IS [133]. Another treatment option is to facilitate the tubular excretion of IS directly through pharmacological intervention, by upregulating channels associated with IS secretion [134]. Developing specific inhibitor of key enzymes involved in the production of indole like TMO or tryptophanase should be developed in the future. Finally, the modulation of AhR activity could be proposed as a potential future target to decrease outcomes in CKD patients.

## Conclusion

Although experimental data do convince us about the toxicity of TRP metabolites, these results must be demonstrated in human cohorts. Indeed, TRP metabolites can be considered only as a marker of kidney failure, and there is a plethora of other retained compounds that could play a role in uremic related complications, either directly or indirectly.

The interaction between diet and gut microbiota must be investigated in CKD. The reduction in protein intake is probably one of the major therapeutic interventions to reduce TRP metabolites production in CKD. Although several bacteria capable of producing TRP catabolites have been identified, in the human gut, the main contributors remain to a large extent unknown. The fecal metagenomic data are still lacking during human CKD. In the future, a combined analysis of profiled microbes (metagenomics) along with the TRP catabolites production (metabolomics) from CKD patients' stool samples seems to be of major importance and may enable the development of specific tools to modulate intestinal microbiota. With all these new strategies, we hope to decrease the progression of not only CKD but also CV diseases, bone diseases, and sarcopenia.

## Introduction

Chronic kidney disease (CKD) progression from early to advanced stages is increasing [1,2] as is albuminuria [2] and its associated death rate [3]. Progression to advanced CKD augments cardiovascular disease (CVD) mortality risk prediction by traditional CVD risk factors, including diet [2,4,5]. Indeed, individuals with CKD suffer premature death more commonly than developing end-stage kidney disease (ESKD) [6]. This enhanced mortality is due predominantly to increased risk for, and earlier onset of, CVD [2], including myocardial infarction [7] and stroke [8]. US populations that are at particularly high ESKD risk are so because of faster progression of prevalent CKD to ESKD rather than to greater CKD prevalence [9], thereby contributing to increasing ESKD prevalence [1]. These observations support an increasing focus on addressing factors that contribute to progression of prevalent CKD to ESKD.

There is growing evidence that an acid ( $H^+$ ) milieu augments CKD progression and that reducing it is kidney protective. Beginning with the most severe end of the spectrum of what we will call “ $H^+$  stress” (Fig. 19.1), treatment of CKD-related metabolic acidosis in patients with plasma total  $CO_2$  ( $PTCO_2$ )  $<22$  mM as recommended by KDIGO guidelines [10] appears to slow decline rate of creatinine clearance [11] and estimated glomerular filtration rate (eGFR) [12,13] in individuals with very low GFR. Correction of less severe

metabolic acidosis (i.e.,  $PTCO_2$  22–24 mM) than that for which current guidelines recommend treatment also appears to slow eGFR decline [14]. In addition, alkali treatment of individuals with reduced eGFR and normal  $PTCO_2$  but eating the high  $H^+$  diets of developed societies [15] appears to slow eGFR decline [16]. These studies support that the full spectrum of  $H^+$  stress ranging from high dietary  $H^+$  with initially normal  $PTCO_2$  to individuals with modestly reduced eGFR and normal  $PTCO_2$  to those with very low eGFR and low  $PTCO_2$  is harmful to kidneys and that its amelioration with dietary alkali slows CKD progression.

## Overview of acid–base balance

Optimal cell and tissue function requires maintenance of “free” body fluid hydrogen ion concentration ( $[H^+]$ ) within a relatively narrow, slightly alkaline, range compared to pure or “neutral”  $H_2O$  with  $[H^+] = 100$  nM or  $100 \times 10^{-9} M = 10^{-7} M = 10^{-7} \text{ mol/L}$ . Because pH of an aqueous solution is its negative log in mol/L, pure or “neutral”  $H_2O$  has pH = 7.00. “Free”  $H^+$  appears to be the component of body  $H^+$  that mediates its physiologic and pathophysiologic actions and so its measurement is of significant interest to clinicians. Nevertheless, most body  $H^+$  is bound to other moieties (i.e., is “buffered”) and so is not “free” in solution. Although buffered  $H^+$  appears to have less direct physiologic and/or pathophysiologic actions, its buffering can cause tissue damage as in consumption of the

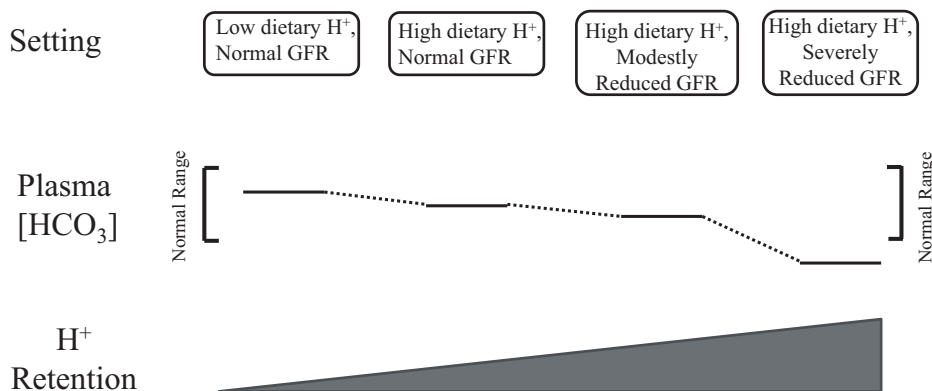

FIGURE 19.1 Theoretical construct for CKD-related acid ( $H^+$ ) stress continuum. CKD, Chronic kidney disease.

0

mineral content of bone [17,18] and the degree of  $H^+$ -buffering might initiate signaling of downstream actions such as increased kidney acidification [19].

Under normal steady-state conditions, multiple systems maintain human plasma  $[H^+]$  within 35–45 nM (pH 7.46–7.35), with “normal” considered  $[H^+] = 40$  nM or pH = 7.40. Clinicians have access to plasma as their “window” into an individual’s acid–base status but other compartments, like the interstitial compartment of extracellular fluid, are also affected by challenges to systemic acid–base and likely play important contributory roles to body responses to these challenges. Acidosis is a process characterized by a net gain of  $H^+$  (caused by gain of  $H^+$  or by loss of buffer, most commonly  $HCO_3^-$ ). On the other hand, the process characterized by a net loss of  $H^+$  (caused by gain of base, typically  $HCO_3^-$ , or loss of  $H^+$ ) is known as alkalosis. Despite daily acid–base challenges from diet and cellular metabolism, various body response strategies typically maintain plasma  $[H^+]$  within the normal range.

Some chronic conditions, including CKD with severely decreased GFR, are associated with such high  $H^+$  accumulation that it is characterized by an initial decrease in plasma bicarbonate (nearly identical, but only slightly less in amount, to  $PTCO_2$ ) concentration ( $[HCO_3^-]$ ), the type of acidosis known as *metabolic* acidosis. Because diets typical of developed societies are  $H^+$ -producing [15], residents in such societies are chronically challenged with dietary  $H^+$ . This “fixed” (or “nonvolatile” to distinguish it from acidosis due to accumulation of carbon dioxide gas that is called *respiratory* acidosis)  $H^+$  is excreted predominantly by the kidney. Some mechanisms employed by kidneys to excrete the ingested  $H^+$  yield the short-term benefit of enhanced  $H^+$  excretion but the long-term detriment of

chronic kidney injury [19]. On the other hand, some individuals with less severely decreased GFR and eating  $H^+$ -producing diets accumulate  $H^+$  at levels that can cause kidney injury [16] yet are insufficient to reduce  $PTCO_2$ , a condition characterized as  $H^+$  retention [20].

### Epidemiology of the spectrum of “ $H^+$ stress”

Most individuals with CKD have sufficient remaining eGFR that enables them to excrete  $H^+$  generated by the  $H^+$ -producing diets of developed societies and endogenous metabolic processes to avoid progressive  $H^+$  retention and consequently do not have steady-state metabolic acidosis [17,21]. Metabolic acidosis of CKD is typically defined as a  $PTCO_2 < 22$  mmol/L due to reduced eGFR (and not to other concomitant conditions like severe diarrhea) and not to respiratory alkalosis [22]. Metabolic acidosis appears after an as yet incompletely determined threshold of accumulated  $H^+$  exhausts multiple compensatory mechanisms [23]. Using the  $PTCO_2 < 22$  mmol/L threshold, most CKD patients do not have metabolic acidosis but its incidence increases as eGFR declines [24]. Overall, about 15% of patients with CKD have metabolic acidosis [24,25] but about 37% of individuals with stage 4 CKD (eGFR 15–29 mL/min/1.73 m<sup>2</sup>) have metabolic acidosis [25]. Individuals with stage 4 CKD have sevenfold higher and those with stage 3 CKD (eGFR 30–59 mL/min/1.73 m<sup>2</sup>) have twofold, respectively, higher odds of metabolic acidosis than those with stage 2 (eGFR 60–89 mL/min/1.73 m<sup>2</sup>) CKD [25]. Individuals with CKD, severely reduced eGFR, and metabolic acidosis have increased urine indices of kidney injury that are reduced with oral alkali-induced improvement of their metabolic acidosis [12].

Reduced residual  $H^+$  excretory capacity, largely determined by level of remaining eGFR, and high dietary  $H^+$  intake contribute to the risk for developing metabolic acidosis. Regarding the former, reduced ammonium excretion appears to identify individuals at risk for developing metabolic acidosis [26]. For example, the risk of incident metabolic acidosis was 2.5-fold higher if ammonium excretion was  $<15$  mEq/day in African American Study of Kidney Disease and Hypertension participants after controlling for GFR and other potential confounders [26]. Regarding the latter, higher dietary  $H^+$  was inversely associated with  $PTCO_2$ , even among individuals without CKD [27–30], and was more likely to cause metabolic acidosis in patients with CKD who had lower compared to those with higher eGFR [31].

Diets typical of developed societies are  $H^+$ -producing because of the preponderance of  $H^+$ -producing meats and refined grains compared to base-producing fruits and vegetables [15]. Individuals eating such diets can have  $H^+$  retention [32–36], with magnitude inversely related to eGFR [34], that is not reflected by plasma acid–base parameters characteristic of metabolic acidosis. Low urine citrate excretion might identify  $H^+$  retention in these patients with CKD but no metabolic acidosis [35,36] and thereby identify them as potential candidates for alkali therapy for kidney protection. Patients with CKD given an increment in dietary  $H^+$  cumulatively excrete less  $H^+$  than ingested, consistent with  $H^+$  retention [17,37]. Individuals with CKD and modestly reduced eGFR without metabolic acidosis despite eating a high  $H^+$  diet nevertheless have increased urine indices of kidney injury that are reduced with oral alkali [16,38].

High  $H^+$  diets given to animals with normal GFR that increase urine  $H^+$  excretion without causing metabolic acidosis by plasma acid–base parameters nevertheless decrease plasma base excess and increase  $H^+$  content of kidney interstitial fluid [39]. Such diets also increase urine indices of kidney injury in animals with normal GFR [23]. Furthermore, high  $H^+$  diets are associated with increased CKD incidence [40]. These data suggest that high  $H^+$  diets cause pathologic  $H^+$  accumulation even in individuals with normal GFR and constitute an early phase of the spectrum of  $H^+$  stress.

The full spectrum of  $H^+$  stress (Fig. 19.1), including (1) high  $H^+$  diets in individuals with normal eGFR, (2) those eating high  $H^+$  diets with reduced eGFR without metabolic acidosis but with  $H^+$  retention, and (3) those individuals with more severely reduced eGFR with metabolic acidosis, all appears to risk  $H^+$ -related kidney injury. The high  $H^+$  diets of developed societies appear to subject these populations to some, at-present unknown, level of CKD risk. Epidemiologic studies support that high  $H^+$  diets increase the progression risk to

ESKD in the general population [41,42]. Those with  $H^+$  retention appear to be individuals for whom oral alkali might provide kidney protection [16] but whose population frequency is unknown at present. The  $\sim 15\%$  of CKD patients with metabolic acidosis are more clearly at CKD risk, current treatment guidelines recommend treatment when  $PTCO_2$  is  $<22$  mM, and alkali treatment appears to be kidney protective [11–13].

### The daily $H^+$ challenge

Fig. 19.2 depicts mechanisms by which the body mitigates fixed  $H^+$  challenges to acid–base balance and thereby helps avoid metabolic acidosis, using strategies, including (1) buffering accumulated  $H^+$ ; (2) sequestering  $H^+$  away from plasma to other fluid compartments, including interstitial and intracellular fluid; (3) neutralization of accumulated  $H^+$  through liver metabolism of endogenous and exogenous base-producing substances like citrate in many plant-based foods, including most fruits and vegetables, and of some organic products of intrinsic metabolism like lactic acid to yield  $HCO_3^-$ ; (4) reduction of net endogenous acid production (NEAP); and (5) urine  $H^+$  excretion (about 1 mEq/kg/day) [43] derived from liver metabolism of  $H^+$ -producing food components (like animal-sourced protein) and some endogenous metabolic products, both of which increase NEAP. Net excretion of fixed  $H^+$  from the body by the kidney yields regeneration of new  $HCO_3^-$  that restores  $HCO_3^-$  lost through titration by added  $H^+$ . Dietary sodium chloride (NaCl) also increases NEAP [44].

Diets typical of developed societies are  $H^+$ -producing because of the preponderance of  $H^+$ -producing animal-sourced food components compared to base-producing plant-sourced components [45]. Animal-sourced compared to plant-sourced food components have more protein and the protein has more sulfur-containing amino acids (e.g., methionine and cysteine) that when metabolized yield sulfuric acid. On the other hand, most fruits and vegetables have fewer sulfur-containing amino acids and potassium salts of organic acids (e.g., citrate) that when metabolized yield  $HCO_3^-$ . Even fresh animal-sourced foods contain various amounts of NaCl, whereas fresh fruits and vegetables are very low in  $Na^+$  and  $Cl^-$ . Processed foods from animal and plant sources constitute an increasing proportion of developed society diets and have added NaCl. Dietary fats and sugars contribute comparatively less to net  $H^+$  production when completely metabolized. The preponderance of animal-sourced to plant-sourced foods, of processed to fresh foods, and high NaCl content all contribute to the  $H^+$ -producing nature of diets typical of developed

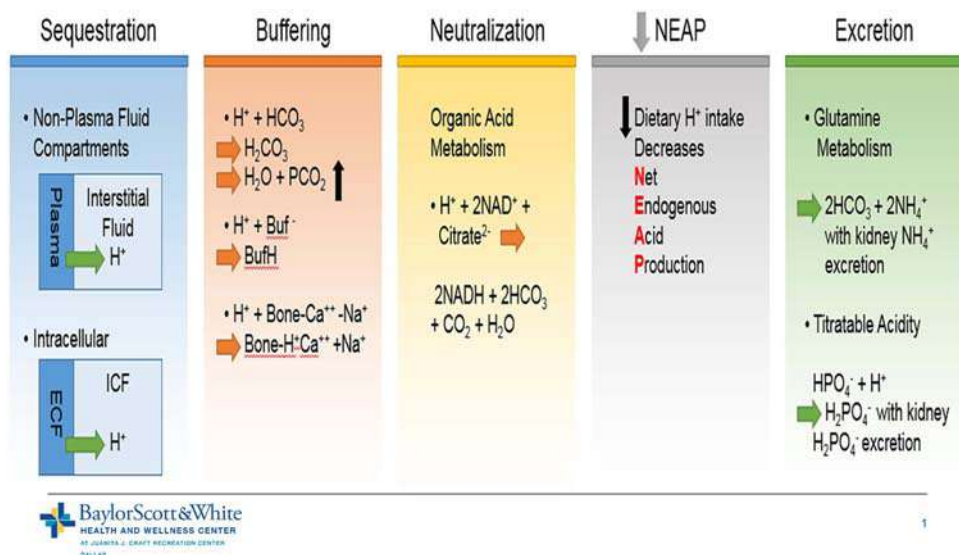

FIGURE 19.2 Body strategies to mitigate added  $H^+$ : maintenance of normal acid–base homeostasis.

Scialla, et al. *Advances in CKD* 20:141, 2013

FIGURE 19.3 Contribution of foods to dietary acid load. DAL, Dietary acid load.

societies. Fig. 19.3 shows comparable acid- and base-producing capacity of selected foods.

Retarding CKD progression through a more alkali-producing diet includes limiting food components that yield  $H^+$  when metabolized like animal protein, including dairy products, most grains, and lentils [45] as well as limiting dietary NaCl that increases NEAP [44]. On the other hand, increasing intake of base-producing foods also

increases dietary alkali but their base-producing capacity varies (see Fig. 19.3). Foods with high base-producing capacity comprise many fruits and vegetables, including raisins, cruciferous vegetables (e.g., broccoli, brussels sprouts, cabbage), leafy greens (kale, spinach, lettuce, collard greens), and soy protein [46]. Substituting base-producing for acid-producing food is a particularly effective strategy for dietary  $H^+$  reduction [15].

## Maintenance of normal acid–base homeostasis

Steady-state maintenance of systemic acid–base status occurs through integration of physiologic mechanisms such as extra- and intracellular buffering processes and collaborative actions of the kidney, liver, lung, gastrointestinal tract, and skeleton. Accordingly, excess  $H^+$  accumulation becomes evident to clinicians through changes in plasma acid–base parameters when the accumulated  $H^+$  exceeds the capacity of normal homeostatic mechanisms and/or because these homeostatic mechanisms are compromised. To understand better how clinicians could manage  $H^+$  accumulation that might exacerbate CKD progression, let us examine the body's various responses to ameliorate untoward effects of accumulated  $H^+$  (Fig. 19.2).

### $H^+$ buffering

*$HCO_3/H_2CO_3$  buffer system.* Adding  $H^+$  to body fluids containing  $HCO_3$  leads to the following:

Consequently, the body effectively removes added  $H^+$  from plasma as  $CO_2$  gas that would otherwise yield  $H^+$  (in a reversal of the abovementioned equation) if it were to accumulate, avoiding the other type of acidosis, respiratory acidosis. This rapidly responsive system works well to minimize the increase in  $[H^+]$  (=decrease in pH) that would otherwise occur in the absence of this elegant system. The price paid is a reduction in plasma  $[HCO_3]$  that kidneys must regenerate through  $H^+$  excretion (see next).

*Non- $HCO_3$  buffers.* “Free”  $H^+$  determines the acid–base effect on cell and tissue function. Binding  $H^+$  to buffers removes it from solution and diminishes its untoward effects. The major non- $HCO_3$  extracellular buffers are hemoglobin and albumin whereas phosphate ion and anionic proteins are the major non- $HCO_3$  intracellular buffers. Patients with CKD commonly have decreased plasma hemoglobin and albumin, compromising extracellular buffering capacity. Quantitatively, most  $H^+$  binding to non- $HCO_3$  buffers occurs intracellularly [47]. Bone calcium carbonate and dibasic phosphate are important buffers for both acute and chronic metabolic acidosis [17]. Animals given an increment in dietary  $H^+$  that increased steady-state urine net acid excretion (NAE) but did not change steady-state plasma acid–base parameters, including  $PTCO_2$ , nevertheless had decreased plasma blood base excess [39], consistent with increased titration of non- $HCO_3$  buffers. By contrast, animals given aldosterone and  $Na_2SO_4$  to increase urine NAE without

an increment in dietary  $H^+$  did not have decreased blood base excess [39], supporting the importance of accumulated  $H^+$ , and not simply ongoing enhanced urine NAE per se, as the factor that led to titration of non- $HCO_3$  buffers.

### $H^+$ sequestration into interstitial fluid

The interstitial component of the extracellular fluid compartment is separated from the vascular component at the tissue level of organs by capillary basement membranes. Kidney interstitium occupies strategic space between peritubular capillaries and kidney tubules, facilitating potential chemical and cytokine communication between plasma and tubule fluid [48]. Microdialysis of the kidney cortex allows assessing of the chemical and cytokine content of the kidney interstitium [49]. Animals given an increment in dietary  $H^+$  that increased steady-state urine NAE but did not change steady-state plasma acid–base parameters, including  $PTCO_2$ , nevertheless had increased  $H^+$  content of kidney cortical interstitial fluid assessed with microdialysis [39]. This  $H^+$  retention in response to dietary  $H^+$  was greater in animals with reduced GFR, even when plasma acid–base parameters were not different from control [23]. Skeletal muscle also had  $H^+$  retention [50], supporting that  $H^+$  retention is a systemic phenomenon, at least in the setting of reduced GFR. Importantly,  $H^+$  retention persisted until the dietary  $H^+$  increment discontinued or was counterbalanced by added dietary alkali [23]. Excess body  $H^+$  sequestered from plasma in interstitial fluid might have the benefit of minimizing  $H^+$  accumulation in plasma with its possible untoward consequences while simultaneously stimulating basolateral kidney tubule mechanisms that enhance  $H^+$  excretion [51–53].

Even large increments in dietary  $H^+$  lead to little to no measurable changes in plasma acid–base parameters in individuals in developed societies, and the small changes that occur typically do so within the normal ranges of clinical laboratories [54]. In addition, increasing  $H^+$  retention that occurs over time with decreasing eGFR is associated with minimal changes in  $PTCO_2$  within the normal range for clinical laboratories [34,36]. These data show the effectiveness of body systems to maintain  $PTCO_2$  in response to an  $H^+$  challenge but also highlight the clinician's challenge to gauge dietary  $H^+$  by plasma acid–base parameters. On the other hand, CKD patients with reduced GFR can have greater increases in plasma  $[H^+]$  and greater decreases in  $PTCO_2$  in response to the same increment in dietary  $H^+$ , even developing metabolic acidosis at levels of dietary  $H^+$  that do not cause metabolic acidosis in patients with higher GFR [31]. Consequently,

clinicians are more likely to recognize metabolic acidosis in patients with lower than higher GFR.

### Endogenous $H^+$ neutralization

The earlier stage in the spectrum of  $H^+$  accumulation that is insufficient to manifest as metabolic acidosis, which we call  $H^+$  retention, nevertheless is sufficient to increase urine levels of substances associated with progressive eGFR decline like endothelin and aldosterone [32] and with increased urine biomarkers of kidney injury [38]. Untoward effects of accumulated  $H^+$  might be ameliorated through neutralization by base derived by metabolism of endogenous and exogenous substances.

The pH-sensitive metabolite citrate is the most abundant organic base equivalent in the urine, is freely filtered at the glomerulus, and the extent of its proximal tubule reabsorption determines its urinary excretion [55]. Secreted  $H^+$  from proximal tubule cells into luminal fluid partially titrates filtered citrate from its trivalent (citrate<sup>3-</sup>) to divalent (Hcitrate<sup>2-</sup>) form, the latter being the preferred substrate for the apical  $Na^+$  dicarboxylate cotransporter, NaDC-1, which reabsorbs it [56,57]. Cytoplasmic ATP citrate lyase metabolizes reabsorbed citrate to oxaloacetate and acetyl-CoA or transports it into mitochondria, where it enters the tricarboxylic acid cycle [58]. When citrate is converted to glucose or  $CO_2$  and  $H_2O$ , 2 or 3  $H^+$  are consumed depending on the valence of the citrate anion, generating 2 or 3  $HCO_3^-$  per citrate molecule. Citrate reabsorption, therefore, equals base gain but its excretion represents base loss [59]. Individuals with reduced eGFR who are eating a high  $H^+$  diet who have  $H^+$  retention but no metabolic acidosis have reduced urine citrate excretion [35,36]. The retained citrate can be metabolized to yield  $HCO_3^-$  to neutralize  $H^+$  that accumulates as eGFR declines [36].

### Reduced NEAP

Individuals with increased NEAP, as might be the case in those eating the high  $H^+$ -producing diets typical of developed societies, reduce NEAP in response to an additional  $H^+$  challenge [60]. By contrast, in individuals with low baseline NEAP, as might be the case in those eating a base-producing diet, this response is blunted [60].

### Enhanced urine $H^+$ excretion

#### **Importance of urine buffers in kidney $H^+$ excretion**

The kidney is the main contributor to excretion of metabolically produced fixed  $H^+$ . Diets of individuals

in developed societies typically produce the equivalent of 60–100 mmol of  $H^+$  daily when metabolized. To excrete 100 mmol of free  $H^+$  in a typical daily urine volume of 1 L would require excreted urine to have a  $[H^+] = 100 \text{ mmol/L} = 100 \times 10^{-3} \text{ M} = 10^{-1} \text{ M} = \text{pH}$  of 1.0 (remember that pH is the negative log of the  $[H^+]$  in mol/L). Because humans are unable to reduce urine pH below 4.0 ( $= [H^+]$  of  $10^{-4} \text{ M}$ ) that is equal to  $[H^+]$  of 0.1 mM = 0.1 mmol/L, to excrete 100 mmol of the daily  $H^+$  generation in urine with pH 4.0 would require  $100 \text{ mmol}/0.1 \text{ mmol/L} = 1000 \text{ L}$  of urine! Hence, kidneys excrete fixed  $H^+$  predominantly as  $H^+$  bound to buffers, not as free  $H^+$  in solution. Quantitatively, ammonium  $[NH_4^+ \text{ from } NH_3 + H^+]$  is the most important urine buffer, particularly in response to increments in dietary  $H^+$ , followed by “titratable acidity,” most of the latter being phosphate ( $HPO_4^{2-} \rightarrow H_2PO_4^-$ ).

#### **Afferent signal for $H^+$ secretion**

The signal(s) that tell kidneys to increase overall urine  $H^+$  excretion in response to (1) an increment in dietary  $H^+$  with normal GFR but in the absence of metabolic acidosis; (2) a reduced functioning nephron capacity (reduced GFR) in the setting of the typical  $H^+$ -producing diet of developed societies (which requires greater per nephron  $H^+$  excretion to achieve the same overall  $H^+$  excretion as when there was a full contingent of functioning nephrons) but no metabolic acidosis; or (3) metabolic acidosis, whatever the underlying GFR, are not clear. Nevertheless, the interstitial fluid compartment appears to be an appropriate one from which an afferent signal might initiate a change in kidney tubule acidification in response to the three settings described. Unlike plasma, interstitial fluid is comparatively protein-free, making its  $[H^+]$  very sensitive to  $H^+$  addition or removal, unlike the highly buffered plasma compartment. Consequently, even small amounts of  $H^+$  added to the interstitial compartment will cause comparatively large changes in  $[H^+]$ . This arrangement makes the interstitial fluid compartment a better one in which to house the “acidstat” than plasma to monitor acid–base status and respond with a signal to change tubule acidification. Were plasma to be the main or exclusive compartment housing the “acidstat,” wide swings in free  $[H^+]$  would have potentially catastrophic consequences to physiologic function. Microdialysis reveals dramatic increases in interstitial  $[H^+]$  induced by increments in dietary  $H^+$  that cause no to comparably small changes in plasma acid–base parameters [39]. We hypothesize that pH sensors such as GPR4 [61] sense these  $[H^+]$  changes in the interstitial fluid compartment. Other or additional signals might be the degree of titration of body buffers [39].

### ***Efferent response leading to increased kidney tubule acidification***

As discussed, metabolically produced  $H^+$  titrates body fluid  $HCO_3^-$ , thereby reducing their concentration. This means that were kidneys to only recover  $HCO_3^-$  that was filtered into its tubules, there would be a progressive body  $HCO_3^-$  deficit because of ongoing metabolic  $H^+$  production with progressive titration and reduction of body fluid  $HCO_3^-$ . This reminds us that kidneys must not only *recover* filtered  $HCO_3^-$  but must also *regenerate* new  $HCO_3^-$  to replace that lost through  $H^+$ -titration as described. These two main kidney tasks are accomplished by  $H^+$  secretion from kidney tubule cells into the tubule lumen. When there is a high amount of  $HCO_3^-$  in the tubule lumen as is the case in the proximal tubule, secreted  $H^+$  titrates luminal  $HCO_3^-$  to  $CO_2$  and  $H_2O$  as described and  $CO_2$  gas diffuses into the cell and is reconstituted to  $HCO_3^-$  by the enzyme carbonic anhydrase. Reconstituted  $HCO_3^-$  transports across basolateral membranes of tubule cells to return to the systemic circulation. When tubule  $HCO_3^-$  content is low as in the distal nephron, most secreted  $H^+$  titrates non- $HCO_3^-$  buffers that are excreted in the urine, mostly as  $NH_4^+$  and titratable acidity. Exit of secreted  $H^+$  from the body as described allows for  $HCO_3^-$  to be regenerated. Overall, the process is called NAE and is equal in amount to  $HCO_3^-$  regeneration. Increments in NAE promoted by increments in dietary  $H^+$  intake are mediated mostly by increased glutamine metabolism with increased urine  $NH_4^+$  excretion and with smaller contributions from increased titratable acidity and decreased urine excretion of  $HCO_3^-$  [21]. Most patients with CKD and reduced GFR can achieve steady-state  $H^+$  excretion enough to avoid progressive metabolic acidosis while eating  $H^+$ -producing diets [17,21]. More advanced GFR reduction in CKD patients, however, is associated with reduced urine  $NH_4^+$  excretion [26,33] that likely contributes to their progression along the  $H^+$  stress spectrum from worsening  $H^+$  retention eventually to metabolic acidosis.

### **Kidney response to $H^+$ accumulation**

Accumulating  $H^+$  activates kidney paracrine hormones, including angiotensin II (AII), aldosterone, and endothelin-1 (ET-1), which all mediate enhanced kidney  $H^+$  excretion [51–53,62,63]. The increment in urine  $H^+$  excretion is mediated predominantly by increased urine ammonium excretion [21]. These responses provide the short-term benefit of increased  $H^+$  excretion but appear to be accompanied by the long-term detriment of progressive CKD progression mediated by interstitial fibrosis and inflammation [64–66].

### ***Angiotensin II***

Dietary  $H^+$  increases kidney AII levels [63] that stimulate distal [63] and proximal [67] tubule  $H^+$  secretion through upregulation of the  $Na^+/H^+$  exchangers NHE3 and NHE2. In contrast, alkali supplementation in CKD patients with metabolic acidosis [14] and in animal CKD models [63] with oral  $Na^+$ -based alkali or base-producing food components reduces elevated kidney AII levels measured by microdialysis or with urine angiotensinogen, the latter being a surrogate of kidney AII levels. Because a persistent increase in kidney AII levels can cause interstitial inflammation, fibrosis, tubular atrophy, and proteinuria that progressively reduce kidney function [68–70], lowering AII levels with dietary  $H^+$  reduction done either with  $Na^+$ -based alkali or base-producing food components appears to be kidney protective. Because AII increases kidney production of ET-1 [71], aldosterone [72], and stimulates ammoniogenesis [67], it might play a central role in CKD progression and its reduction with dietary alkali might be key component of kidney protection in CKD.

### ***ET-1 and aldosterone***

Kidney levels of both ET-1 and aldosterone are elevated in experimental CKD models [62,66] and urine levels are elevated in patients with CKD [32]. These substances help mediate increased nephron acidification of animals with reduced nephron mass [62] but contribute to progressive GFR decline in these same models [66]. Dietary  $H^+$  reduction with oral alkali [50,65] or base-producing diets [50] reduce kidney levels of these substances in these experimental CKD models. In addition, oral  $Na^+$ -based alkali reduces urine excretion of both in patients with CKD [32]. These data support that the kidney protective benefit of dietary  $H^+$  reduction is mediated in part through reduced kidney levels of ET-1 and aldosterone.

### ***Ammoniogenesis***

Although total ammonium excretion decreases as CKD worsens [26,33] due to reduced ammoniogenesis [73], ammonia generation per functioning nephron increases, helping to maintain  $H^+$  excretion in the setting of reduced eGFR [21,73]. This adaptive response helps with the short-term need to increase per nephron  $H^+$  excretion in the setting of reduced nephron mass and continued high dietary  $H^+$  intake. Nevertheless, over the long term, this adaptive response contributes to progressive nephron loss because ammonia activates the alternative complement pathway within the kidney, increasing inflammation and increasing tubulointerstitial damage [64]. Oral  $Na^+$ -based alkali reduces ammoniogenesis in experimental CKD models and

thereby reduces interstitial injury with amelioration of subsequent GFR decline [64].

### Alkali management strategies to retard CKD progression

The most recent practice guidelines from the National Kidney Foundation [74] recognize two strategies by which to reduce  $H^+$  stress: reduce NEAP and/or neutralize accumulated acid with  $Na^+$ -based alkali. Regarding reducing NEAP with diet, the guidelines suggest doing so in adults with CKD stages 1–4 “through increased dietary intake of fruits and vegetables (2C) in order to reduce the rate of decline of residual kidney function.” The “2C” grading acknowledges the need for more published research in this area such that the true effect may be substantially different from the estimate of the effect. Regarding reducing NEAP with  $Na^+$ -based alkali, the guidelines recommend doing so in adults with CKD stages 3–5 “through increased bicarbonate supplementation (1C) in order to reduce the rate of decline of residual kidney function.” The “1C” grading again acknowledges the need for more published research in this area so that the true effect may be substantially different from the estimate of the effect. Regarding a target level of serum  $HCO_3^-$  to seek to achieve with  $Na^+$ -based alkali, the guidelines offer the *opinion* that “it is reasonable to maintain serum bicarbonate levels at 24–26 mmol/L.” The “opinion” grading recognizes that the available evidence is insufficient to offer a more definitive target. Recommended  $NaHCO_3$  doses from earlier recommendations [10] range from 0.5 to 1.0 mmol  $HCO_3^-$  or its equivalent per kg lean body weight daily.

Recognizing that  $H^+$  accumulation contributes to CKD progression, we categorize approaches to reduce  $H^+$  accumulation as a strategy by which to retard CKD progression into three general categories:

- Reduce  $H^+$  intake.
- Neutralize accumulated  $H^+$ .
- Remove accumulated  $H^+$ .

### Reduce $H^+$ intake: dietary management of $H^+$ accumulation

As noted, typical diets in developed societies are  $H^+$ -producing, due largely to the proportionately greater amount of animal-sourced proteins (which are  $H^+$ -producing) than plant-sourced proteins (many of which are base-producing). Plant-sourced dietary protein interventions not only reduced  $H^+$  production from sulfur- and phosphate-containing amino acid metabolism, improved metabolic acidosis [75], and reduced  $H^+$  retention [35] in individuals with CKD,

but also improved weight, blood pressure, and other cardiovascular risk parameters [75,76]. The strategy discussed next supports diet as the foundational “food first” [77] approach to management of patients with CKD, including avoiding or managing  $H^+$  accumulation, with pharmacologic therapy as adjunctive to diet.

These dietary strategies mainly include:

1. reducing  $H^+$ -producing food components like animal-sourced protein,
2. limiting dietary NaCl, and
3. adding base-producing food components like fruits and vegetables.

High dietary  $H^+$  contributes to metabolic acidosis in individuals with severely reduced GFR [15,31] and to  $H^+$  retention in those with more modest eGFR reduction [32,34–36]. The above mentioned three strategies and/or combinations thereof can accomplish dietary  $H^+$  reduction.

### Removing/limiting $H^+$ -producing dietary components

Acid contents of many foods have been published [45] and can be used to limit intake of high  $H^+$ -producing foods for individuals with CKD. These  $H^+$ -producing food components include mainly animal-sourced protein. When animal-sourced protein is prescribed, fresh rather than processed food is recommended because of lower NaCl and  $Na^+$  phosphate that are often added to such food to preserve shelf life can increase NEAP [44]. Individuals with CKD given a vegetarian diet supplemented with keto-analogs had better eGFR preservation than equivalent participants given a low-protein diet with a mixture of animal- and plant-sourced proteins [78].

### Limiting dietary NaCl

As noted, dietary NaCl increases NEAP [44] and so its reduction contributes to dietary  $H^+$  reduction. When fresh fruits and vegetables were added to diets of individuals with CKD and metabolic acidosis, study participants substituted these food components given at no cost for more expensive, processed food components that they had previously purchased, leading to decreased NaCl intake [14,38]. Therefore increasing the proportion of fresh plant-sourced foods in the diet, which are naturally low in NaCl, might help reduce NaCl intake, additionally reducing the dietary  $H^+$  load.

### Adding base-producing food components like fruits and vegetables

Dietary base-producing fruits and vegetables given to nondiabetic patients with stage 4 CKD and serum  $HCO_3^- < 22$  mEq/L in amounts designed to reduce

their dietary  $H^+$  intake by 50% improved metabolic acidosis comparable to similar individuals given  $NaHCO_3$  [75]. Estimated GFR was not different between both interventions and both treatments were associated with lower-than-baseline urine indices of kidney injury, including albumin, *N*-acetyl-beta-*D*-glucosaminidase (NAG), and TGF- $\beta$  [75]. In other studies, individuals with CKD stage 3 and low normal serum  $HCO_3^-$  (22–24 mEq/L), a level higher than that for which earlier KDIGO guidelines recommended treatment [10], given fruits and vegetables to incorporate into their ad-lib diets had comparable improvement of metabolic acidosis and comparable eGFR preservation [14]. In addition, both alkali treatments decreased three markers of kidney damage, including urinary albumin, NAG, and urine angiotensinogen, a surrogate of kidney AII levels [14]. Supplementation with fruits and vegetables also reduced  $H^+$  retention in individuals with CKD, reduced eGFR, but no metabolic acidosis [35]. Fruits and vegetables prescribed in amounts to provide alkali equivalent to 50% of their calculated dietary  $H^+$  load amounted to adding two to four cups of fruits and vegetables to their daily ad-lib diets [14,35,75]. Participants in these studies were carefully selected to be at very low risk to develop hyperkalemia in response to the increased  $K^+$  load that accompanies fruits and vegetables. Analysis of published data, however, provides little evidence to support that restricting food-based potassium intake in CKD patients prevents hyperkalemia [79]. Nevertheless, clinicians should use caution when considering prescribing fruits and vegetables to CKD patients, particularly those with very low GFR. Other investigators showed that the more that individuals with CKD adhered to a Dietary Approaches to Stop Hypertension diet, one that emphasizes fruits, vegetables, whole grains, and limits red meat, the lower the CKD incidence [80] and the lower the risk of CKD progression to ESKD [81]. Furthermore, such diets appear to reduce mortality in individuals with CKD [82].

### Neutralize accumulated $H^+$ intake: $Na^+$ -based alkali

KDIGO guidelines [10] recommend sodium bicarbonate ( $NaHCO_3$ ) for metabolic acidosis in CKD because it is effective, relatively well tolerated, widely available, and inexpensive. Clinicians prescribe potassium bicarbonate less commonly, except in patients who require substantial  $HCO_3^-$  replacement (like proximal renal tubular acidosis) in whom  $HCO_3^-$  administration causes large  $K^+$  losses. Potassium bicarbonate should be avoided in patients with very low GFR (<25% of normal) due to the risk for  $K^+$  retention with

hyperkalemia. Because the liver metabolizes citrate to yield  $HCO_3^-$ , clinicians sometimes prescribe  $Na^+$  citrate for patients unable to tolerate  $NaHCO_3$ . The use of  $Na^+$  citrate is limited by its unpleasant taste, comparatively high expense, and because it promotes gastric aluminum absorption [83]. Consequently,  $NaHCO_3$  is the  $Na^+$ -based alkali salt upon which we will focus.

Sodium bicarbonate is water soluble and when taken orally rapidly reacts with gastric hydrochloric acid (HCl) to form  $NaCl$ ,  $CO_2$ , and  $H_2O$ . Excess  $HCO_3^-$  that does not neutralize gastric  $H^+$  rapidly empties into the small intestine and is absorbed. Reaction of  $NaHCO_3$  with gastric HCl increases gastric lumen pH, stimulating gastric parietal cells to secrete more HCl into the gastric lumen. Secretion of HCl into the gastric lumen leads to  $HCO_3^-$  extrusion into perigastric capillaries and eventually into the systemic circulation to increase extracellular  $[HCO_3^-]$  if it is reduced. If extracellular  $[HCO_3^-]$  attains a level that exceeds the kidney tubule maximum for reabsorption, excess  $HCO_3^-$  is eliminated in the urine. Consequently, most individuals without severely reduced eGFR ( $>25$  mL/min/1.73 m<sup>2</sup>) can excrete excess  $HCO_3^-$  and thereby avoid metabolic alkalosis.

Orally administered  $NaHCO_3$  at low-to-moderate doses ( $<0.3$  mEq/kg lean body weight daily) has few serious side effects when given to individuals with CKD [84]. Most side effects are due to the release of  $CO_2$  gas after contact with gastric  $H^+$  and include belching, gastric distension, and flatus. Higher doses ( $>0.5$  mEq/kg lean body weight daily) might cause volume retention and possibly exacerbate hypertension and other  $Na^+$ -sensitive comorbid conditions in patients with very low GFR (CKD stages 4 and 5). Nevertheless, investigators did not observe a significant difference between the  $NaHCO_3$  and control group regarding worsened hypertension requiring higher dose drug therapy as well as worsening edema requiring increased loop diuresis [11]. Others reported no  $NaHCO_3$  influence on effects like bloating, flatulence, stomach upset, nausea, edema, shortness of breath, and no patient hospitalizations in patients with CKD and eGFR 15–45 mL/min/1.73 m<sup>2</sup> who received escalating doses of  $NaHCO_3$  over 6 weeks [85]. On the other hand, individuals with CKD stages 3 and 4 treated with  $NaHCO_3$  required increasing diuretic doses to manage  $Na^+$  retention [86]. Although an increment in oral  $NaHCO_3$  caused less  $Na^+$  retention, weight gain, and blood pressure increase than an equal increment of oral  $NaCl$  when study participants with creatinine clearance  $<20$  mL/min/1.73 m<sup>2</sup> ate a very  $NaCl$ -restricted (10 mmol/day) diet [87], equal  $NaHCO_3$  and  $NaCl$  increments caused comparable  $Na^+$  retention, weight gain, and blood pressure increase when participants ate a  $NaCl$ -containing diet (100 mmol  $Na^+$ /day)

more commiserate with typical dietary NaCl intake in developed societies [88]. Recognizing that most individuals with CKD have comorbid, Na<sup>+</sup>-sensitive states like hypertension that might be exacerbated by the Na<sup>+</sup> accompanying Na<sup>+</sup>-based alkali, clinicians should use caution when prescribing Na<sup>+</sup>-based alkali to those with CKD and comorbid Na<sup>+</sup>-sensitive conditions, particularly when high doses are required to achieve desired outcomes [89].

The optimal daily dose of NaHCO<sub>3</sub> that provides kidney and other organ protection yet minimizes side effects remains to be determined. KDIGO guidelines recommend 0.5–1.0 mEq of NaHCO<sub>3</sub>/kg body weight daily in patients with PTCO<sub>2</sub> < 22 mmol/L [10]. Tolerance and compliance of those using NaHCO<sub>3</sub> depend on its galenic form. Tablets and capsules are well tolerated and the dose can be better controlled. There is no chemical difference between supermarket baking soda and NaHCO<sub>3</sub> powder or tablets in pharmacies but pharmacies can professionally advise individuals regarding interactions, side effects, and warnings. Also, dosing with powdered NaHCO<sub>3</sub> is less precise than tablets and its temperature sensitivity makes storage of NaHCO<sub>3</sub> challenging. Consequently, the better recommendation for CKD patients is NaHCO<sub>3</sub> prescribed and purchased as tablets or capsules from a pharmacy rather a supermarket.

### Remove accumulated H<sup>+</sup> intake: H<sup>+</sup>-binding polymers

Advances in drug technology include polymers that selectively bind substances in the gastrointestinal tract and remove them from the body with feces. One such polymer selectively binds gastrointestinal HCl and removes it from the body, thereby increasing PTCO<sub>2</sub> and doing so as soon as within 24 hours of administration [90]. With continuous use the increase in PTCO<sub>2</sub> was sustained over 12 [91] and 52 weeks [92]. Ongoing testing will determine if this and/or other H<sup>+</sup>-binding polymers will be approved for treatment of metabolic acidosis and therefore added to the available treatment options.

### How might clinicians approach management of H<sup>+</sup> stress, as a kidney protective intervention, in individuals with CKD within the context of the three mechanistic strategies?

Because dietary strategies described improved the most severe end of the spectrum of H<sup>+</sup> stress, that is, metabolic acidosis [14,75], ameliorated H<sup>+</sup> retention in individuals with reduced eGFR but no metabolic

acidosis [35], and might prevent metabolic acidosis [31] and H<sup>+</sup> retention [20] in individuals with reduced eGFR, it seems prudent to begin treatment of H<sup>+</sup> stress with interventions that limit dietary H<sup>+</sup> intake and/or include them as adjunctive interventions. Were these dietary strategies alone not to be successful in achieving the treatment goal, it seems reasonable to then recommend H<sup>+</sup> neutralization using Na<sup>+</sup>-base alkali as tolerated. Employing this next step of H<sup>+</sup> neutralization only after limiting dietary H<sup>+</sup> intake offers the potential benefit of minimizing the dose of Na<sup>+</sup>-base alkali necessary to achieve the treatment goal. If polymer drugs that remove H<sup>+</sup> from the gastrointestinal tract become available for clinical use, it appears reasonable to include them in the armamentarium of drugs used to treat H<sup>+</sup> stress.

## Conclusion

The spectrum of H<sup>+</sup> stress appears to contribute to enhanced CKD progression that is increasing ESKD prevalence. Treating H<sup>+</sup> stress by limiting dietary H<sup>+</sup> intake and/or neutralizing accumulated H<sup>+</sup> with food-based and/or Na<sup>+</sup>-based alkali appears to be an effective kidney protective strategy. Dietary H<sup>+</sup> reduction treatment of H<sup>+</sup> stress promises to not only provide kidney protection but also to reduce the elevated cardiovascular risk in CKD when accomplished with base-producing foods like fruits and vegetables.

# Nutritional management of sodium, chloride, and water in kidney disease and kidney failure

Michel Burnier Sr.

Service of Nephrology and Hypertension, University Hospital, Lausanne, Switzerland

## Introduction

Among all physiologic parameters involved in the homeostasis of human body to maintain what Claude Bernard named the *milieu intérieur* [1], water and sodium balances are probably the mostly tightly regulated. Indeed, in human, multiple mechanisms contribute to maintain sodium and water balance in a narrow range despite large interindividual variations in salt and water intake. These mechanisms include the control of water and salt intake, through behavioral and neuroendocrine pathways, and a precise regulation of sodium and water excretion, mainly through the kidney and its ability to finely tune urinary sodium and water elimination. Thereby, extracellular fluid volume (ECFV), which consists of plasma volume and interstitial fluid volume and represents 25% of body weight, and intracellular fluid volume (ICFV), 33% of body weight, are maintained relatively constant in steady-state conditions. The regulation of ECFV is characterized by the fact that small changes ( $\sim 2\%$ ) in plasma osmolality are sufficient to activate a regulatory response through osmoreceptors, thirst, and vasopressin neurons [2], whereas larger changes in volume ( $\sim 10\%$ ) are necessary to trigger low-pressure baroreceptors and to induce a correction of fluid volumes through fluid intake and a reduction of fluid excretion [3]. Owing to the major role played by the kidney in the regulation of fluid and electrolyte excretion, it is not surprising that alterations in renal glomerular and/or tubular functions, as observed in kidney diseases, have a major impact on the ability to maintain sodium and water balance. In this chapter, we shall discuss water and sodium homeostasis in normal conditions and in chronic kidney disease (CKD) at

different levels of glomerular filtration rate (GFR), including end-stage kidney disease (ESKD). We shall also discuss the clinical implications of salt and water excess and the potential benefits of reducing salt intake on renal disease progression and on the occurrence of cardiovascular complications. At last, we shall present the most recent recommendations for water and electrolyte management in CKD.

## Regulation of sodium, chloride, and water in healthy conditions

### Sodium

Sodium intake is highly variable among human individuals and across populations. Thus in a 2010 survey of sodium consumption around the world, Powles et al. reported sodium intakes ranging between 1.5 and more than 6 g Na/day that would correspond to intakes of salt (sodium chloride) ranging between 3 and more than 15 g/day [4]. The Prospective Urban Rural Epidemiology study reported similar high levels of sodium intake, and these latter were associated with an increased risk of mortality and cardiovascular events [5].

Today, humans on an unrestricted diet ingest sodium in a large excess of the amount needed to maintain fluid and electrolyte homeostasis. Interestingly, in contrast to animals, humans do not have a true appetite for salt [6]. Thus for example, salt depletion does not induce a craving for salt in humans [6]. In fact, the mechanisms responsible for the regulation of sodium intake are multiple and not yet fully understood. Several physiological factors play a role in the modulation of sodium intake

such as the renin–angiotensin system, aldosterone, the baroreceptor input, and sodium content of the cerebral spinal fluid, which are known to stimulate salt intake in some circumstances [3]. However, cultural as well as environmental and genetic [7] factors are also important determinants of salt intake in populations. Of note, the need for sodium varies during the human life with increased requirements during some periods of growth (children and adolescents) and during pregnancy. The reason why salt consumption is so high today in humans might also be associated with the activation of brain reward pathways [3,8]. Thus one could consider sodium intake per se as a potentially modifiable behavioral risk factor for cardiovascular and renal diseases.

Once ingested, sodium is distributed in the ECFV where it represents the main cation. Sodium balance is maintained essentially by the kidneys, which modulate its excretion through several neurohormonal and tubular ion transport systems, such as the renin–angiotensin–aldosterone system [9,10], the sympathetic nervous system [11], and atrial natriuretic peptides [12], but also prostaglandins [13], endothelin [14], adducing [15], uromodulin [16], and many others.

The mechanisms whereby the kidney maintains sodium balance have been studied essentially in protocols in which individuals are maintained on a low- or high-sodium intake, respectively [17–19]. The renal response to a marked reduction of sodium intake is characterized by an intense reabsorption along the proximal tubule and the loop of Henle, a reabsorption in the distal tubule and a fine-tuning of sodium excretion occurring in the collecting duct mediated by aldosterone [10,18]. In addition, mechanisms linking renal hemodynamics and tubular functions such as the glomerulo-tubular balance and tubule-glomerular

feedback contribute to the maintenance of sodium and fluid balance. In healthy subjects, sodium excretion is not regulated by blood pressure (BP). Thus high-salt/low-salt protocols have shown that in healthy subjects, there is no parallel change in BP when salt intake is modified indicating that their BP is salt-resistant as shown in Fig. 20.1. However, this pressure–natriuresis relationship may sometimes differ with parallel changes in sodium intake and BP indicating salt-sensitivity. In that case, BP may be either salt resistant (parallel shift only) or salt sensitive (parallel shift with a flattening of the slope). These patterns are common in elderly, in African American and in individuals with hypertension, diabetes mellitus, and CKD as will be discussed later in this chapter [20]. The high-salt/low-salt crossover studies also demonstrated that although the neurohormonal response is quite rapid, sodium balance and a new steady state are effectively reached only after 3–4 days. With these renal mechanisms of regulation of sodium excretion, a nearly total conservation of sodium may occur in extreme physiological conditions.

This purely “kidney-centric” view of the regulation of sodium and fluid balance was reappraised following the observation of 12 healthy men who participated to flight simulation studies for 105 and 520 days [21]. In these studies, men were submitted to three levels of sodium intake (6, 9, and 12 g NaCl/day) for months and studied in metabolic conditions with multiple hemodynamic, hormonal, and urine measurements during the study. The main observation of these clinical experiments is that despite a constant salt intake urinary sodium excretion varies and there are aldosterone-dependent, weekly rhythms in daily sodium excretion, which result in periodic sodium storage. In addition, there are changes in total-body sodium, which follow longer rhythm periods (monthly or even longer)

FIGURE 20.1 Illustration of the pressure–natriuresis relationship in normal subjects, in hypertensive patients with a normal renal function and in patients with hypertension and a reduced renal function. Note that hypertensive patients with a normal renal function may also be salt-sensitive. This is common for example in elderly, subjects of African origin, and patients with monogenic forms of hypertension.

without parallel changes in body weight and extracellular water. These latter changes are related to the fluctuations of urinary aldosterone and to cortisol. These findings actually modify the concept of salt balance demonstrating fluctuations in sodium excretion with periods of storage and excretion even in steady state. Moreover, the data support the concept that sodium can be stored in other tissues like skin and muscles [22,23]. Thus the same authors demonstrated using magnetic resonance ( $^{23}\text{Na}$ -BOLD-MRI) that sodium is actually stored in a nonosmotic way in the skin and muscles in humans [24,25]. Thus even healthy subjects are able to inactivate a substantial proportion of the sodium they receive when infused with hypertonic saline [26]. Glycosaminoglycans have many negative charges enabling the nonosmotic storage of sodium in the interstitium [27]. More recent data have demonstrated the involvement of immune cells, mainly macrophages, in the skin, that sense the hypertonic accumulation of sodium, and activate the tonicity-responsive enhancer-binding protein to initiate expression and secretion of vascular endothelial growth factor C [28,29] (Fig. 20.2). This latter increases electrolyte clearance via cutaneous lymph vessels and increases endothelial nitric oxide synthase expression in blood vessels thereby contributing to the regulation of sodium homeostasis and BP.

These data on new mechanisms involved in the regulation of sodium balance have modified the general concept of two compartments being in equilibrium

adding another compartment in which sodium can be stored nonosmotically, thereby participating in the long-term maintenance of sodium balance [30].

## Chloride

Chloride is the main anion present in the extracellular compartment. In general, changes in plasma and urinary chloride excretion follow those of sodium and when the variations in chloride are not proportional to those of sodium, they rather reflect alterations in the acid–base status. Chloride is absorbed in the small and large intestine and is secreted abundantly by the stomach. Chloride can accumulate in the skin as well. Precisely 90% of chloride is excreted in the urine and the other 10% are eliminated in stool and sweat. In the early tubular segments of the nephron, chloride is transported through the same transporter systems than sodium but this is not the case in the more distal segments of the nephron where specific chloride transport pathways exist [31,32]. Chloride's main function is to concentrate urine. Indeed, reabsorption of chloride occurs actively in the loop of Henle and this establishes the transport gradient needed for the “counter-current” urine concentrating mechanism.

## Water

As it is the case for sodium intake, fluid intake is highly variable among adult individuals essentially

**FIGURE 20.2** Skin mechanism for buffering dietary salt. Under normal conditions,  $\text{Na}^+$  binds to negatively charged GAGs in the dermal interstitium, without commensurate water, allowing high concentrations of  $\text{Na}^+$  to accumulate in the skin. During salt loading the  $\text{Na}^+$ -binding capacity of GAGs is exceeded and interstitial hypertonicity develops. This leads to an influx of macrophages, which release an osmosensitive transcription factor (TonEBP). This induces the secretion of VEGF-C in an autocrine manner, leading to lymphangiogenesis. The enhanced lymphatic network increases  $\text{Na}^+$  transport back into the circulation, for eventual removal by the kidneys, preventing a blood pressure rise with salt loading. TonEBP, Tonicity-responsive enhancer-binding protein. From Selvarajah V, et al. Skin sodium and hypertension: a paradigm shift?. *Curr Hypertens Rep* 2018;20 (11):94, with permission. due to personal habits and cultural and environmental factors. Using urine output as an indirect marker of fluid intake, several surveys have demonstrated that urinary volume excretion varies enormously within and between individuals [33–35]. In healthy individuals the majority of fluid intake (80%) is ingested through beverages and fluid present in food and a smaller volume (about 300 mL) is produced by the cell metabolism (Table 20.1). Fluid output is regulated by the kidney (about 60% of fluid intake), the skin (about 30%), and fecal losses. The respective contributions of these excretion pathways depend on age, gender, fluid intake, sodium excretion, climate, environment temperature, exercising [34].

Regulatory mechanisms contributing to water balance are essentially those associated with hypovolemia and/or increases in plasma tonicity. Thus the predominant mechanism of regulation is thirst and activation of the vasopressin and renin–angiotensin system, mediated in part by the detection of changes in plasma volume by the low-pressure baroreceptors, located in the superior and inferior vena cava and the atria of the heart. Any change in plasma tonicity and central blood volume will initiate a global response that includes adjustments in thirst and sodium ingestion.

TABLE 20.1 Components of normal daily water balance in the adult.

Water intake	
Source of water	Volume (mL/day)
Ingested as fluid	Variable <sup>a</sup> , usually 1000–2000
Ingested as solid food	Usually 800–1000
Production from oxidative metabolism	Usually 200–300
Total	2000–3300
Water output	
Routes of water loss	Volume (mL/day)
Urine	Variable <sup>b</sup> , usually 1000–2200
Sweat	Negligible, except in hot environment or after exercising, when several thousand mL can be lost
Stools	100
Skin	450 <sup>c</sup>
Respiratory tract	450
Total	2000–3300

<sup>a</sup>The amount of water ingested depends on cultural influences as well as serum osmolality.  
<sup>b</sup>Depends on what is needed to achieve water balance.  
<sup>c</sup>These are pure water losses. The losses are influenced by humidity and body temperature.

Vasopressin is the main hormone regulating water excretion through its effects on V2 receptors located in principle cells in the late distal tubule and collecting ducts. Vasopressin secretion is stimulated not only by hypovolemia or a high plasma osmolality but also by angiotensin II, nausea, pain, and many centrally acting drugs. In recent years, experimental developments have evidence new pathways stimulating vasopressin secretion and thirst, one of them being located in the tongue, that is, the acid-sensing taste receptor cells (TRCs) expressing otopetrin 1 on type III presynaptic TRCs [36]. Another observation is the role of the median preoptic nucleus neurons activity, which serves as a central detector to discriminate fluid ingestion from solid ingestion and, hence, promote acute satiation of thirst through the subfornical organ and other downstream targets [36]. This enables to cut the thirst feeling before tonicity or volume balance has actually been restored.

In summary, the human body is extremely well organized to fight against dehydration and minor changes in plasma tonicity. Some systems may seem redundant but are important to maintain the homeostasis of extracellular and ICFVs and protect our organs, mainly the brain, from excessive fluctuations in volume or tonicity.

Regulation of sodium, chloride, and water in kidney diseases (stages 3–5)

Regulation of sodium balance in chronic kidney diseases

Considering the central role of the kidney in maintaining fluid and electrolyte balance as discussed previously, it is not surprising that acute as well as chronic alterations in kidney functions affect its regulatory capacities. Nevertheless, the ability of patients with CKD to maintain salt balance on a regular sodium intake usually remains rather intact until GFR is less than 15 mL/min. Below a GFR of 15 mL/min, kidneys are often unable to increase sodium excretion sufficiently to maintain a satisfactory sodium balance. In that case, salt intake must be reduced to avoid any increase in plasma volume.

In CKD patients, quantitative changes in physiologic factors involved in the maintenance of sodium balance occur. This is the case for aldosterone, the sympathetic nervous system, natriuretic peptides, peritubular physical factors. Thus as the number of nephrons is reduced, sodium excretion per remaining nephron increases, leading to an increase in the fractional excretion of sodium [37], thereby contributing to the so-called magnification process observed

in CKD [38]. Thus salt-sensitive hypertension is highly prevalent in CKD stages 3–5 [39]. The elevated BP increases urinary sodium excretion as the pressure–natriuresis relationship is shifted to the right (Fig. 20.1). In addition, nonosmotical storage of sodium in the skin and muscle appears to be greater in patients with CKD, in elderly subjects and in CKD patients receiving hemodialysis when compared to healthy individuals [24,40,41] and this may represent another mechanism protecting CKD patients from sodium overload, volume expansion, and excessive elevation of BP.

In more advanced CKD a salt-wasting state has been described, characterized by an incapacity to lower urinary sodium excretion on a very low-salt diet and leading to a net sodium loss [42]. Therefore these patients are more vulnerable in case of acute sodium depletion. The same holds true for acute volume depletion. However, this does not seem to be the case when sodium depletion is gradual [43]. Taken together, these two observations suggest that the kidneys cannot adjust immediately to marked and acute changes in sodium intake but can adequately adjust to a decrease in sodium intake if these changes occur slowly. This is actually the main characteristic of CKD patients in whom any sudden excess in sodium intake can cause volume expansion, hypertension, and edema whereas sudden decreases in sodium intake can induce volume depletion and aggravation of renal function due to prerenal azotemia.

Of note, the anion accompanying sodium appears to have an important influence on the sodium-wasting phenomenon. Thus renal sodium wasting is accentuated if sodium is ingested as  $\text{NaHCO}_3$  (sodium bicarbonate) rather than  $\text{NaCl}$ . This was demonstrated when patients with various forms of CKD were fed a diet in which the source of sodium was either 100 mM/day of  $\text{NaCl}$  or 100 mM/day of  $\text{NaHCO}_3$  [44]. During  $\text{NaCl}$  feeding, patients maintained a satisfactory sodium balance. However, during  $\text{NaHCO}_3$  feeding, progressive negative sodium balance developed. This suggested a decreased capacity of the kidney to reabsorb sodium, unless sodium is accompanied by an anion that can easily be reabsorbed, such as chloride.

### Regulation of water balance in chronic kidney diseases

The limitations in the ability to regulate water excretion in patients with CKD are rather similar to those observed with sodium. An impaired ability to both concentrate and dilute urine is documented in all forms of CKD stages 3–5. It occurs earlier and more severely in primary tubule-interstitial renal diseases

compared to primary glomerular diseases. However, in either form of CKD, when GFR falls to less than 20 mL/min in adults, the maximum urine concentration barely exceeds plasma osmolality (300 mOsm/L) and the minimum urine osmolality is approximately 200 mOsm/L. Therefore in advanced kidney disease, an osmolar load of 600 mOsm/day requires a urine output of about 2 L/day. Consequently, urine output is usually higher than normal in advanced kidney disease. It is only when ESKD is reached that urine volume would be expected to be lower than normal regardless of fluid intake.

The impaired renal concentrating ability in CKD is related to tubular dysfunction, changes in medullary structure and tonicity, single-nephron hyperfiltration, and vasopressin resistance. These dysfunctions lead to higher urine volume to excrete the daily osmotic load (600–900 mOsm/day). Thus CKD patients will become dehydrated and hypernatremic if water intake is insufficient. On the other hand, an excessive water intake in advanced CKD may cause volume overload and hyponatremia. Dysnatremia reflecting changes in water intake and excretion have been frequently reported in CKD patients. In a study of the prevalence and incidence of dysnatremia and its associated mortality in 655,493 US veterans with nondialysis-dependent CKD, 13.5% of patients had episodes of hyponatremia (serum  $\text{Na} < 136$  mmol/L), and only 2% had hypernatremia (serum  $\text{Na} > 145$  mEq/L) [45]. During a median follow-up of 5.5 years, 26% of them had at least one episode of hyponatremia, and 7% had at least one episode of hypernatremia. Management of such patients is problematic if they become severely hyponatremic due to the high mortality risk [45].

### Regulation of sodium and water balance in kidney failure (CKD stage 5D)

In patients with ESKD needing a substitution therapy such as hemodialysis or peritoneal dialysis, the lack of renal clearance leads to sodium and water overload and maintaining a balance is a challenge. Thus using bioimpedance spectroscopy, 25%–30% of patients undergoing maintenance hemodialysis or peritoneal dialysis have a fluid overload of more than 2.5 L [46,47] and in one study, only about one-third of patients on hemodialysis had a fluid overload of less than 1.1 L [47]. As discussed earlier, sodium accumulates in tissue in osmotically active (ECV, bones) and inactive forms (skin, muscles, arteries). Recent data have confirmed that sodium accumulation in skin and muscle occurs in hemodialysis patients [40,48] and in a greater magnitude in patients with type 2 diabetes [48]. The tissue accumulation of sodium can be partly removed during hemodialysis

sessions [40,48]. In hemodialysis the accumulation of sodium in muscle might have some significant impact on glucose metabolism favoring the development of insulin resistance [49]. Recently, Canaud et al. have elegantly reviewed the impact of these new pathogenic mechanisms controlling sodium and fluid balance in patients on maintenance hemodialysis [50].

### Clinical implications of salt and water excesses in kidney diseases

In CKD patients the accumulation of salt and fluid, as well as salt and volume depletion, have important clinical consequences, which will depend on the severity of the kidney impairment. The most frequent complications associated with marked alterations in sodium and fluid balances are the following: (1) development of hypertension, (2) kidney disease progression as reflected by changes in proteinuria and GFR, (3) development of target organ damages such as left ventricular hypertrophy or vascular stiffening, and (4) increased risk of cardiovascular and total mortality.

#### Stages 3–5

##### Hypertension

The prevalence of hypertension is high in patients with CKD ranging between 10% and almost 100% depending on the type of renal disease and its severity, as BP increases when renal function is worsening [39]. As discussed earlier in this chapter, most CKD patients have a salt-sensitive form of hypertension associated with an expanded ECFV and a high-sodium intake [51]. According to Guyton's hypothesis, the elevation of arterial BP enables to eliminate sodium and thereby to lower BP. However, this compensatory mechanism may become ineffective in advanced kidney disease. Thus one of the main characteristics of hypertension in CKD is the progressive loss of the dipping pattern of BP profile as GFR declines [52–54]. In one study in 26 CKD patients with glomerular disease and various degrees of kidney impairment, Fukuda et al. showed that the duration of nighttime hypertension increased progressively as renal function deteriorated suggesting that impaired daytime natriuresis leads to a progressive compensatory increase in nocturnal BP to maintain sodium balance [55]. The absence of nocturnal dipping in CKD patients is a particularly important feature as it increases the risk of renal disease progression, cardiovascular events, and mortality [56,57]. It is also the most common cause of uncontrolled masked hypertension in patients with kidney diseases as shown in a post hoc analysis of the African American Study of Kidney Disease and Hypertension

FIGURE 20.3 Comparison of clinic SBP and nighttime ambulatory SBP in 377 participants with controlled blood pressure in the African American Study of Kidney Disease Cohort Study. In this subgroup, 70% had masked hypertension because of elevated nighttime BP. SBP, Systolic blood pressure. From Pogue V, et al. Disparate estimates of hypertension control from ambulatory and clinic blood pressure measurements in hypertensive kidney disease. *Hypertension* 2009;53 (1):20–7, with permission (free access).

Collaborative Research Group [58] (Fig. 20.3). In CKD patients with masked nocturnal hypertension, the prevalence of proteinuria and left ventricular hypertrophy was higher than in patients with well-controlled hypertension [58]. In addition to the abovementioned mechanisms, an excessive sodium intake may affect BP and the cardiovascular system through its direct effects on oxidative stress, inflammation, and endothelial function [59].

Does a reduction of sodium intake lower arterial BP in hypertensive CKD patients? Several small- and middle-size randomized controlled studies have demonstrated that reducing sodium intake lowers BP in CKD patients [60]. Thus in a Cochrane analysis performed in 2015, McMahon et al. found eight randomized controlled trials (RCTs) assessing the effect on BP of two or more levels of salt intake in people with various CKD stages. The study duration ranged between 1 and 26 weeks and the total number of patients was 258. The mean reduction in 24 hours urinary sodium excretion was approximately 105 mmol/24 h and decreases in systolic and diastolic BP were, respectively,  $-8.75$  and  $-3.70$  mmHg [60]. On a low-sodium diet, less antihypertensive drugs were used. In a more recent study, Saran et al. investigated the effects of a low-sodium intake ( $<2$  g Na/day) administered for 4 weeks in a crossover design in 58 patients with CKD stages 3–4. Significant changes in whole-body extracellular volume and calf intracellular volume, urinary sodium excretion, body weight, and 24-hour systolic BP [ $-10.8$  mmHg; 95% confidence interval (CI),  $-17.0$  to  $-4.6$ ] were observed on the low-salt

regimen [61]. The latest metaanalysis by Garofalo et al. reported similar results when combining the results of eleven RCTs and information from 738 patients with CKD stages 1–4 [62]. In an interesting study, Meuleman et al. randomized 138 patients to usual care or usual care plus an intervention comprising education, motivational interviewing, coaching, and self-monitoring of BP and sodium [63]. At 3 months, significant decreases in urinary sodium excretion and both office and ambulatory BP were observed. However, at 6 months, there were no differences in sodium excretion and ambulatory BP in the two groups. These results demonstrate the difficulties to maintain a low-sodium diet in the real life, outside a study protocol as it will be discussed later in this chapter.

Taken together, the data available so far demonstrate that reducing sodium intake in patients with CKD stages 1–4 contributes to lower BP and reduce ECFV.

An excessive sodium intake has also a critical role in the management of hypertension in CKD patients. Indeed, as in hypertensive patients with a normal renal function, a high-sodium intake has been shown to blunt the BP-lowering efficacy of several antihypertensive classes, mainly blockers of the renin–angiotensin system (ACE inhibitors and angiotensin receptor blockers) and diuretics [64]. However, this is not the case for calcium antagonists, which have a natriuretic effect [64,65]. Therefore for these drugs to have their maximal antihypertensive efficacy, it is preferable that patients avoid a high-salt diet. Similarly, drugs inducing a sodium retention such as nonsteroidal antiinflammatory drugs or inhibitors of cyclooxygenase type 2 will reduce the efficacy of the same antihypertensive drug classes and induce a rise in BP particularly in patients with a reduced renal function [66,67]. The recent recommendations for the treatment of hypertension in CKD emphasize the important role of diuretics (thiazides or loop diuretics depending on the CKD stage) in the management of hypertension in patients with a reduced renal function [68,69]. Single pill combinations containing a blocker of the renin–angiotensin system and either a diuretic or a calcium channel blocker are now strongly recommended as first-line therapy, based on the results of recent large randomized clinical trials such as the ACCOMPLISH trial [70].

Overall, the data presented previously emphasize the risk of hypertension associated with a high-salt intake. In contrast, increasing water intake has a modest, if any, effect on BP unless patients have a very advanced CKD. Regarding the impact of salt and water depletion on BP, one has to mention that chronically reducing salt intake down to 2 g Na/day was not associated with orthostatic hypotension or severe hypotension in CKD patients. Yet, acute episodes of

salt and water depletion may be associated with hypotension and a transient aggravation of renal function. This is the reason why patients with CKD should remain well hydrated and should avoid rapid and large changes in sodium intake.

### **Proteinuria**

Proteinuria is a recognized marker of kidney disease and of the risk of CKD progression [71,72]. In the general population, proteinuria is strongly associated with the risk of cardiovascular or all-cause death [73]. In most clinical studies having assessed the impact of salt intake on BP, an effect on proteinuria was also observed indicating that patients on the lower sodium diet had lower albuminuria or proteinuria [60,63]. In the 2018 metaanalysis of Garofalo et al. [62], a modest reduction of salt intake was associated with a reduction of albuminuria/proteinuria in patients with CKD stages 1–4. One of the landmark trials is the crossover trial (HONEST) performed by Slagman et al., which included 52 patients with proteinuric CKD (mean protein excretion 1.6 g/day, mean creatinine clearance 70 mL/min), already treated with lisinopril [74]. In this study, patients received four treatments given in random order, each for 6 weeks, that is, a low-sodium diet with placebo, a low-sodium diet with valsartan, a regular-sodium diet with placebo, and a regular-sodium diet with valsartan. Compared with the regular-sodium diet, the low-sodium diet decreased mean daily protein excretion significantly and the reduction in urinary protein excretion was greater than that obtained with the addition of valsartan (51% vs 21%). This observation demonstrates that reducing sodium intake in CKD patients with proteinuria is actually more effective than intensifying the blockade of the renin–angiotensin system to lower proteinuria. Another study has shown that sodium restriction is as effective as adding a diuretic on top of blockers of the renin–angiotensin system to reduce proteinuria [75].

Today, the administration of a blocker of the renin–angiotensin system is recommended as first-line therapy in proteinuric CKD patients with or without hypertension [68,69]. However, in this patient population, one should note that the antiproteinuric effect of blockers of the renin–angiotensin system or nondihydropyridine calcium channel blockers is offset with a high-salt intake, even when BP control seems appropriate, and conversely, the antiproteinuric efficacy of these drug classes is enhanced with salt restriction. Taken together, these data demonstrate sufficient evidence supporting a reduction of sodium intake to decrease proteinuria in CKD.

The role of water intake on proteinuria is less clear, at least in humans. Indeed, in animal studies, an increase in water consumption has been shown to

lower BP and proteinuria and improve survival in 5/6 nephrectomized rats [76]. In a recent observational cohort study of 2182 participants aged older than 20 years, there were no differences in urinary protein excretion between those subjects who had a urinary volume greater than 3.5 L/24 h and those with a urine output of less than 2.1 L/24 h [77]. In healthy human subjects the administration of vasopressin has been reported to increase proteinuria [78] but this was not the case in patients with a syndrome of inappropriate antidiuresis [79]. Thus as far as one knows, the impact of a high or low-water intake on urinary protein excretion remains poorly understood and more clinical studies are needed before any recommendation could be made.

### ***Kidney disease progression***

Hypertension and proteinuria are two major determinants of kidney diseases progression. Since sodium impacts both parameters, it should have an influence on the rate of decline of renal function in patients with or without CKD. As reviewed by Smyth et al., several small clinical studies reported a more rapid decline in renal function in CKD patients on a high-sodium diet but whether a low-sodium diet actually retards the progression of renal diseases has not been convincingly demonstrated [80]. In non-CKD patients the situation is even more controversial as renal function decline aggravation has been reported in patients on a low-sodium intake suggesting a J-shaped curve relationship between sodium intake and the rate of renal function decline [80]. In a large analysis, Smyth et al. have assessed the relationship between 24 hours urinary sodium excretion and GFR decline of 30% or more or the need for chronic dialysis in the 28,879 high cardiovascular risk patients having participated in the ONTARGET and TRANSCEND trials [81]. The mean follow-up of these patients was 4.5 years. Interestingly, no significant association between urine sodium and any marker of renal disease progression was found whereas positive associations were found with urinary potassium excretion, a higher potassium excretion having a favorable impact on renal outcomes. In the Chronic Renal Insufficiency Cohort Study the prospective analysis of the data of 3939 CKD participants demonstrated that a high urinary sodium and potassium excretion is associated with an increased risk of CKD progression [82]. In a post hoc analysis of the REIN trials, the progression of the decline in GFR was evaluated in 500 CKD patients with nondiabetic nephropathies according to the level of salt excretion [83]. There was a threefold increase in the incidence of ESKD in patients with the highest urinary sodium/creatinine ratio. In addition, the high-salt intake blunted the antiproteinuric effect of ramipril. In a post hoc

analysis of the RENAAL and IDNT trials, Lambers Heerspink et al. found that the risk of renal events was significantly reduced by 43%, not changed, or increased by 37% for each tertiles of increased sodium intake. This suggests that a low-sodium intake potentiates the renal protective benefits of blockers of the renin–angiotensin system in CKD patients with type 2 diabetes [84]. Thus in the absence of a specifically designed randomized trial in CKD patients, it is difficult to propose evidence-based recommendations on how much sodium CKD patients should eat to slow down the progression of their kidney disease but some low-level evidence does exist to support sodium restriction.

Whether fluid intake affects the decline in renal function in CKD patients remains controversial. In a community-based study of 2148 subjects with a baseline GFR > 60 mL/min/1.73 m<sup>2</sup>, Clark et al. reported that the decline in kidney function was significantly slower in those with the higher (>3 L/day) versus lower (<1 L/day) urine output in a preliminary feasibility study [85]. However, this finding was not confirmed in the larger trial conducted by the same authors and published in 2018 [86]. In two cross-sectional population-based studies conducted in Australia, a high water intake (>3.2 L/day), calculated based on a food frequency questionnaire, also appeared to afford renal protection when compared to a low-water intake [87]. However, in a post hoc analysis of the MDRD trial, in which GFR and 24-hour urinary volume were measured at several time points, a high urinary volume was associated with a more rapid decline in renal function and thus in CKD patients with or without polycystic kidney disease (PKD) [88]. Thus the authors recommended letting thirst guide the fluid intake of CKD patients and not to encourage them to drink more. Nevertheless, today, a high water intake belongs to the recommendations for the prevention of CKD progression in some renal diseases such as PKD, although it may be less effective than a vasopressin antagonist [89]. Of note, plasma copeptin levels have been shown to correlate positively with urine osmolality and the development of renal cysts and negatively with estimated GFR in a population-based study [90].

### ***Cardiovascular morbidity and mortality***

In patients with CKD a high-sodium intake (above approximately 6 g/day) is associated with a higher risk of having a cardiovascular event, including heart failure, myocardial infarction, and stroke [91]. However, prospective studies are lacking demonstrating that lowering sodium intake actually reduces cardiovascular morbidity and mortality in CKD patients and the possibility of a J-shaped curve cannot be excluded.

Few data are available on the impact of fluid intake on morbidity and mortality in the general population or in CKD patients. In California, Chan et al. reported a lower incidence of coronary events in subjects who had a high daily intake of water (five or more glasses/day) compared with those who had a low daily water intake (two or fewer glasses/day). The relative risks were of 0.46 (95% CI: 0.28, 0.75;  $P$  trend = .001) in men ( $n$  = 8200) and 0.59 (95% CI: 0.36, 0.97) in women ( $n$  = 12,017). In a more recent analysis of NHANES III, Wu et al. found that subjects in the highest quartile of fluid intake had the lowest overall mortality, but cardiovascular mortality was similar across quartiles of fluid intake [77]. However, so far, no prospective RCT supports a recommendation to drink more than 2.5–3 L/day. In any case, these volumes of water are difficult to achieve and maintain by CKD patients and there may be a risk of inducing hyponatremia.

## Dialysis

### Hypertension

Hypertension is common in CKD stage 5D on hemodialysis or peritoneal dialysis. Indeed, 50%–85% of hemodialysis patients and nearly 30% of peritoneal dialysis patients are hypertensive according to various studies and registries [92–94]. Hypertension is associated with an increased risk of morbidity (left ventricular hypertrophy, coronary heart disease) and mortality in CKD stage 5D [94–97]. One study has shown that increase in BP during hemodialysis is associated with a reduced 2-year survival, particularly in those patients with a relatively low BP at baseline [98]. Fluid overload and chronic salt loading leading to a high interdialytic weight gain belong to the main factors contributing to the development and maintenance of hypertension in patients on hemodialysis [94,99]. As mentioned previously, sodium accumulates in tissues (skin and muscles) of patients treated by hemodialysis and this may contribute to the development of hypertension and other cardio-metabolic complications such as glucose intolerance, left ventricular hypertrophy, malnutrition, and accelerated vascular aging [50]. Hypertension is less frequent in patients on frequent hemodialysis or longer hemodialysis sessions, which enable a better correction of fluid overload and subtraction of sodium excess. In a randomized controlled study in hemodialysis patients, sodium restriction to 2 g/day, compared to the usual diet, was not found to lower BP but reduced significantly the inflammatory profile of patients [100]. However, in another study of 12 patients on peritoneal dialysis and 15 patients on hemodialysis, significant decreases in BP were observed when patients were placed on a strict salt restriction [101]. In a retrospective

analysis of 307 patients on peritoneal dialysis, BP was comparable in patients on a low- and high-sodium intake [102].

### Cardiovascular morbidity and mortality

In ESKD, sodium and fluid overloads are recognized factors increasing the patients' morbidity and mortality although results are somewhat discordant. Thus in a post hoc analysis of 1770 patients of the Hemodialysis (HEMO) Study, the Cox regression analysis found that higher baseline dietary sodium was independently associated with a greater all-cause mortality [103]. In contrast, the retrospective cohort study in 303 patients on peritoneal dialysis in Japan found the opposite, a low-sodium intake being significantly associated with a higher overall and cardiovascular mortality [102]. However, the results of this latter study might be biased, as sodium intake was associated with higher lean body mass, younger age, and higher BMI. A low-sodium intake may also be associated with a poor nutrition, which, per se, increases mortality in patients on dialysis.

Results are more consistent when assessing the impact of fluid overload on morbidity and mortality. In the international cohort study in 8883 hemodialysis patients from the European MONDO database, fluid overload was found to be a significant risk factor for short-term mortality and the impact of fluid overload on mortality was even greater when combined with the patients' inflammatory status [47]. Several other studies have confirmed the associations of fluid overload with mortality but also between fluid overload and left ventricular hypertrophy, endothelial dysfunction, inflammation, and malnutrition [104–108].

## Recommendations for the nutritional management of sodium, chloride, and water

### Determination of sodium intake and water balance

The management of salt and fluid intake should start with the identification of the amount of sodium and fluid ingested by patients, and this is challenging. Indeed, the recommended method to assess sodium and fluid intake in clinical practice is the collection of urine over 24 hours. This method, which assumes that the patient has a stable salt intake and that the urine output reflects the oral intake, is known to have some limitations such as incomplete collection and reluctance of patients to repeat the procedure. The recent work of Titzé's group has added other limits to 24 hours urine collections demonstrating that 10%–15%, and perhaps more, of the ingested salt is actually stored in tissues and hence not recovered in the 24 hours urine [21,24,109].

Based on their observations of substantial variability of sodium excretion despite a fixed intake, they now recommend performing several 24 hours urine collections to have a more detailed assessment of sodium intake. However, this is hardly feasible in clinical practice. For that reason the measurement of sodium excretion in single 24 hours urine collections will probably remain the gold standard in every day practice. Frequency food questionnaires might help in some circumstances, but other health-care professionals than physicians should perform them, because it is time-consuming.

The development of  $^{23}\text{Na}$ -MRI is an interesting new approach to evaluate how much sodium and water have accumulated in tissues. This technique might become useful to manage CKD patients, in particular those on maintenance dialysis [50]. However, so far, this costly approach remains in the field of clinical research and more data are needed to validate its clinical potential in preventing target organ damage and eventually mortality in patients with hypertension and/or kidney disease. Today, several research programs combining different renal functional MRI techniques to measure renal flow, tissue oxygenation, or tissue fibrosis are under clinical investigations to improve the global management of CKD patients [110].

The clinical assessment of fluid overload is particularly important in patients on maintenance dialysis although an excess of fluid can be problematic already in patients with earlier CKD stages. In hemodialysis the assessment of fluid overload is essential to determine the “dry weight” of patients, this latter being an important determinant of BP and cardiovascular complications such as left ventricular hypertrophy [50,111,112]. Today, several techniques are available to estimate ECFV. This includes ultrasound of the inferior vena cava or of the lung to assess water accumulation in the interlobular septa of the lung, the use of volume sensors, and mainly the multifrequency bioimpedance spectroscopy, which is an easy-to-use and affordable technique to monitor fluid status and its changes as recently reviewed by Canaud et al. [50].

### Recommendations for sodium and fluid intake according to international societies

Recommendations for salt intake have been published for the general population, for patients with hypertension, diabetes, heart failure, and specifically for patients with CKD stages 1–5D. The targets proposed by the different societies and their justifications are summarized in Table 20.2. Of note, since most randomized controlled studies in CKD defined the low low-sodium sodium arm as a sodium intake below 80–100 mmol/day, that is, a sodium intake of less

than 2–2.3 g Na/day, it is not possible to evaluate whether lower levels of sodium intake are actually more or eventually less beneficial for CKD patients.

In the general population the recommended salt intake is <2.0 g Na/day (or <5 g NaCl/day) according to the World Health Organization [113] and <2.3 g Na/day (or >5.75 g NaCl/day) according to the 2010 Dietary Guidelines for Americans and the American Heart Association (AHA) [114]. However, the pertinence of this target was challenged by the National Academies of Sciences, Engineering, and Medicine (NASEM, former Institute of Medicine) [118]. Yet, in 2019, a low threshold at <1.5 g Na/day was proposed by this institution for adults older than 18 years with no difference between men and women except during pregnancy [115,118].

For patients with hypertension, European guidelines from the European Society of Cardiology and European Society of Hypertension recommend a sodium intake of <2.0 g Na/day or less than 5 g of salt per day [68]. In the United States the recent AHA and American College of Cardiology guidelines and the US Department of Agriculture recommendations propose a sodium consumption of less than 1.5 g Na/day (3.75 g NaCl/day) in patients with hypertension or a reduction of the usual sodium intake by at least 1 g Na/day [69]. Of note, in chronic diseases, including hypertension, diabetes, and CKD, the NASEM proposed a sodium intake of 2.3 g Na/day [115].

In the nephrology community the 2012 recommendations made by the Kidney Disease: Improving Global Outcomes group were <2 g Na/day (>5.75 g NaCl/day) and those of the K/DOQI group were of <2.4 g Na/day for nondialyzed patients and <2.0 g Na/day for patients on maintenance dialysis [116,117]. In the 2019 update of the Clinical Practice Guideline for Nutrition in CKD, the recommendations are to limit sodium intake to less than 100 mmol/day (or <2.3 g Na/day) to reduce BP and improve volume control in CKD stages 3–5 (nondialyzed) (level of evidence 1B) and patients on dialysis (1C). The main target is to lower BP and to reduce proteinuria in CKD stages 3–5 patients and to better control weight gain and volume control in patients on maintenance hemodialysis (CKD stage 5D) (Prof. Kopple, personal communication).

Therefore the actual recommendations tend to support an apparent consensus to limit sodium intake between 2 and 2.3 g Na/day or 5 and 6 g NaCl/day. The only stricter recommendation is coming from the United States regarding the general population and the management of hypertensive patients with a target of 1.5 g of sodium or 3.75 g NaCl/day. In patients with CKDs, one has to emphasize that some patients actually need a higher salt intake (>7 g NaCl 24 hours) because of the characteristics of their kidney diseases, which promote salt excretion

**TABLE 20.2** International recommendations of sodium intake for the general population, hypertensive patients, and chronic kidney disease (CKD) patients.

	Sodium (g/day)	Sodium (mmol/day)	NaCl (g/day)	Justification
<b>General population</b>

and induce sodium depletion and hypovolemia if not compensated. This is the case, for example, of patients with medullary cystic disease, Fanconi's syndrome, or hypercalcemia-associated renal impairment.

Regarding water consumption, recommendations are much wider and depend on several external factors such as climate, physical activity, and dietary content of water. The recommendations for the general population differ substantially between the United States and Europe with a total daily fluid intake of 2.7 and 3.7 L/day for women and men, respectively, in the United States and 2–2.5 L in Europe [119]. In CKD patients, there are no clear recommendations except for patients with kidney stone diseases or PKD who are encouraged to drink more than 3 L daily, the higher being the better [120]. A high fluid intake may also help preventing urinary tract infections [121]. However, in the study by Clark et al., patients with a

urine output >3.7 L had the best prognosis in terms of kidney disease progression as discussed earlier [85] although in a larger prospective trial, the same authors found that increasing fluid intake by 0.6 L did not affect CKD progression in patients with CKD stage 3 [86]. Thus some authors advocate that fluid intake should just follow thirst, avoiding an excess of sugar-containing drinks. Avoiding a daily oral fluid intake below 1.5 L is probably a reasonable recommendation in CKD patients.

### The challenges of reducing salt intake and increasing fluid intake

In prospective interventional trials, interventions to lower salt intake were of relatively short duration (from 2 weeks to 3 months) and were applied using a

strictly controlled protocol. The application of guidelines is much more difficult when the restriction has to be maintained for years. Indeed, nonadherence to nutritional recommendations is quite common due to numerous reasons, including a lack of motivation and knowledge, the absence of positive feedback, and the social conditions of patients. Studies have actually demonstrated that, even with the help of nurses practitioners [122,123], cooking sessions [124] or education, and self-management interventions [63], there are quasi no long-term changes in lifestyle in CKD patients. Thus in Meuleman's study, 24 hours urinary sodium excretion decreased by 30.3 mmol/24 h at 3 months from a baseline of 159 mmol/24 h but was back to baseline (157 mmol/24 h) at 6 months [63].

In fact, one has to acknowledge that the effort asked to CKD patients is relatively important. Indeed, sodium intake in the US population averages 3.4 g Na/day (8.5 g NaCl/day) and surveys in CKD populations have shown an average sodium intake clearly above 9 g NaCl/day in most countries, meaning that patients should reduce their salt intake by about 3.5–4.5 g NaCl/day [63,64,123,125–127]. To achieve such targets the implementation of the new recommendations on sodium intake in patients with kidney diseases and kidney failure should be accompanied by practical information, which guide patients in their efforts to achieve the recommended target. The changes

should be introduced step by step and practical tips should be provided (Table 20.3) [129]. An excellent example is given by D'Alessandro et al. who published practical tips for the nutritional management of CKD patients in Italy [128] (Fig. 20.4). In patients on maintenance hemodialysis, in addition to reducing salt intake

TABLE 20.3 Tips to reach the desired sodium target in daily life.

1. Move the salt shaker away from the table
2. Cook pasta, rice, and cereals without salt (add in smaller amount directly on cooked food)
3. Use spices (e.g., herbs, lemon, vinegar, hot, pepper) instead of salt or salt-containing condiments (e.g., ketchup, mayonnaise, mustard, barbecue sauce)
4. Look for the amount of sodium on food labels
5. Choose fresh or plain frozen foods and low-salt bread
6. Cut back on frozen dinners, canned soups, packaged mixes, cured meat, and fish (e.g., ham, bacon, anchovies, salmon)
7. Choose fresh (e.g., mozzarella) rather than seasoned cheese
8. Rinse canned foods (e.g., tuna) to remove some sodium
9. Abolish salty snack foods (e.g., chips, nuts)
10. Consume 4–5 servings per day of fruits or vegetables

and increasing sodium clearance during dialysis, other more enjoyable procedures may help subtracting sodium from tissues such as increasing perspiration through the skin using hot water baths or Hamman sessions [130].

## Conclusion

Reviews, metaanalyses, and guidelines on fluid and/or sodium intake in patients with kidney diseases or kidney failure, generally, conclude that the level of evidence is weak. The main reasons for this conclusion are that data on hard endpoints such as total or cardiovascular mortality and renal disease progression come mainly from observational studies or post hoc analyses and not from solid prospective RCTs. This is indeed the case, but is not a sufficient reason not to intervene on sodium intake because there are stronger evidence demonstrating that CKD patients can benefit from reducing their salt intake. Thus on a low-salt diet, patients with CKD stages 3–5 have a lower BP, a lower degree of inflammation, less proteinuria, and less target organ damages. Moreover, they need less antihypertensive drugs to control their BP and their progression toward ESKD may be retarded. In patients on maintenance dialysis, a lower sodium and fluid intake is associated with less interdialytic weight gain, less target organ damages, less thirst, a reduced need for antihypertensive drugs, and a better tolerance of hemodialysis sessions. Altogether, these favorable impacts of reducing sodium intake should contribute to improve the quality of life of patients with CKDs.

However, sodium and water should not be considered independent factors without considering other electrolytes and nutritional factors. Thus the interaction between sodium and potassium appears to be very important to prevent cardiovascular events in CKD. In early stages of renal diseases, potassium intake should be sufficient because potassium has been shown to blunt the effects of a high-sodium intake on BP and cardiac complications [131] and may retard GFR decline [132]. Moreover, recent data suggest that the urinary Na/K ratio is a predictive factor for kidney function decline in the general population [133] as well as in patients with early CKD stages [134]. In more advanced CKD stages (3b–5), however, patients should become more careful with their potassium intake because of the risk of hyperkalemia and increased mortality rate.

Sodium intake should also be considered in the context of the overall nutritional status of CKD patients. Physicians should carefully check that sodium restriction does not lead to wasting by reducing food taste and hence appetite, as it occurs in elderly patients on maintenance hemodialysis.

# Management of potassium in chronic kidney disease and acute kidney injury

David E. St-Jules<sup>1</sup> and Anuja Shah (Pradip)<sup>2,3,4</sup>

<sup>1</sup>Department of Nutrition, University of Nevada, Reno, NV, United States <sup>2</sup>Division of Nephrology and Hypertension, Harbor-UCLA Medical Center, Torrance, CA, United States <sup>3</sup>David Geffen School of Medicine at UCLA, Los Angeles, CA, United States <sup>4</sup>Lundquist Institute at Harbor-UCLA, Torrance, CA, United States

Potassium is a key component of the electrochemical system that drives many cellular processes in the body. The distribution of potassium between the intracellular and extracellular fluid compartments, referred to as the *internal potassium balance*, is tightly controlled by adjusting potassium ion channels in the plasma membrane. Under basal conditions, potassium has a steep intracellular: extracellular concentration gradient of approximately 35:1 (Table 21.1), which is maintained by the sodium–potassium ATPase ( $\text{Na}^+ - \text{K}^+$  pump). Of the 45 mEq (1760 mg)/kg of potassium in the body, about 98% is stored intracellularly [1]. As the main intracellular cation, potassium is particularly important in establishing the membrane potential required for action potentials in neurons and muscle cells.

Loss of kidney function, medications, and dialysis can disrupt potassium balance in people with chronic kidney disease (CKD) or acute kidney injury (AKI), causing serious, and sometimes fatal potassium disorders. Because the extracellular fluid compartment has a relatively low volume and potassium concentration, the potassium concentration gradient is far more sensitive to shifts in extracellular potassium concentrations (Table 21.1). As a result, potassium disorders are driven and defined based on serum potassium concentrations.

Kidney disease may be associated with both low and high serum potassium concentrations [2]. In hyperkalemia the higher-than-normal extracellular potassium concentration reduces the potassium concentration gradient and resting transmembrane potential of contractile cells. The resultant effects on action potential generation are responsible for the muscular and cardiac complications associated with hyperkalemia. Hypokalemia has

the opposite effect on resting membrane transmembrane potentials but has similar negative effects of muscular and cardiac function.

## Potassium balance in health

### External potassium balance

Total body potassium content is determined by the difference in potassium inputs and outputs, known as the *external potassium balance*. The primary source of body potassium is diet, and the main routes of potassium loss and excretion are stool, sweat, and urine. In healthy adults, dietary potassium intakes greatly exceed losses in stool and sweat, and external potassium balance is maintained by adjusting potassium excretion in urine.

Dietary intake of potassium in the United States and Canada is typically in the range of 1500–3500 mg/day. Potassium in food is either in the free, ionized form, or bound to small organic or inorganic anions. These latter potassium salts dissociate in the digestive tract, and the majority of dietary potassium is rapidly absorbed in the proximal small intestine via unregulated passive mechanisms, primarily paracellular diffusion, and solvent drag, which are nonsaturated across normal dietary intake levels [3,4].

Unabsorbed dietary potassium is excreted in stool. The overall amount potassium excreted in stool depends on dietary potassium and fiber intakes. When consuming a low-fiber diet, 10%–15% of dietary potassium intake is excreted in stool [5]. As dietary fiber intake increases, stool potassium excretion increases

TABLE 21.1 Effects of intracellular fluid (ICF) and extracellular fluid (ECF) potassium on the potassium gradient.

	ICF	ECF	ICF:ECF
Volume	28 L	14 L	2:1
Normal [K <sup>+</sup> ]	140 mEq/L	4 mEq/L	35:1
+20 mmol K <sup>+</sup> (ICF)	141 mEq/L	4 mEq/L	35:1
+20 mmol K <sup>+</sup> (ECF)	140 mEq/L	5.4 mEq/L	26:1

20 mmol K<sup>+</sup>  $\approx$  780 mg (moderate potassium meal).

roughly in proportion to increases in stool output (400–500 mg/100 g stool) and can account for up to a third of potassium output [5]. In a controlled feeding study in young men, average potassium excretion in stool increased by 25 mg for every 1 g of whole grain fiber added to the diet [5]. It is unclear whether the increase in fecal potassium excretion caused by dietary fiber is due to reduced absorption in the small intestines, increased secretion in the large intestines, or a combination of both.

Potassium losses in sweat are generally small (<500 mg/day) and largely unrelated to potassium intake [6]. Exercise and heat exposure can increase potassium losses in sweat substantially, and under extreme conditions, sweating can contribute to potassium depletion [7]. However, the effects are typically transient, as adaptation to exercise and acclimation to heat reduce potassium losses in sweat back to near-normal levels [7].

The kidneys are responsible for excreting excess dietary potassium to maintain external potassium balance. Every day, the kidneys filter and reabsorb approximately 25–30 g of potassium from plasma. Although the majority of potassium is reabsorbed in the proximal segments of the nephron, urinary potassium excretion is fine tuned to maintain external potassium balance by controlling the rate of potassium secretion in the distal convoluted tubules and collecting ducts [8]. This system is highly adaptive and robust, being able to adjust potassium excretion from almost zero to more than 10 g/day [9].

Potassium secretion in the distal nephron is determined by (1) the presence and activity of potassium ion transport proteins, and (2) the electrochemical gradient for potassium [8].

Although the mechanisms involved in potassium secretion have been identified (Table 21.2), the pathways involved in sensing changes in dietary potassium intakes remain unknown. Because urinary potassium excretion rates adapt to match dietary potassium intakes without changes in serum potassium concentrations, an as-yet unidentified feed-forward signaling pathway originating from the gastrointestinal (GI) system has been proposed [10].

If serum potassium concentrations become abnormal, feedback mechanisms become activated to help maintain potassium homeostasis. In addition to the direct effect of serum potassium concentrations on potassium's electrochemical gradient [11], serum potassium directly, and via aldosterone-mediated pathways, adjusts the activity of potassium ion transporters, and the delivery of sodium and water to the distal nephron [12]. Despite their overlapping regulatory mechanisms, renal handling of sodium and fluid is decoupled from potassium such that potassium excretion by the kidneys is largely unaffected by sodium and fluid status (referred to as the “aldosterone paradox”) [8].

### Internal potassium balance

Internal potassium balance represents the potassium concentration gradient that is central to potassium-related functions and disorders. This balance is regulated by modifying the presence and activity of potassium ion transporters in the plasma membrane of cells, particularly the Na<sup>+</sup>–K<sup>+</sup> pumps. Several factors have been shown to impact the internal distribution of potassium, including insulin, catecholamines, acid–base balance and serum osmolality.

The typical meal contains enough potassium to raise serum potassium concentrations by approximately 1–2 mEq/L (Table 21.1). And yet, in healthy individuals, serum potassium concentrations remain relatively stable postprandially due to insulin-mediated increases in Na<sup>+</sup>–K<sup>+</sup> pump activity that drives potassium intracellularly [13]. High-potassium foods tend to be rich in glucose and/or amino acids, which stimulate insulin secretion. However, when potassium is consumed without an insulin response, as seen with potassium supplements or untreated insulin-dependent diabetes mellitus, potassium accumulates in the extracellular compartment until the kidneys can excrete it [13].

Postprandial potassium clearance is dependent on insulin, and, therefore, insulin-stimulating macronutrients. However, the pathways involved are primarily

TABLE 21.2 Determinants of potassium secretion and reabsorption in the distal nephron.

Promotes secretion (excretion)	Mechanisms	Promotes reabsorption (retention)
High serum $[K^+]$	Increases potassium gradient; activates potassium transporters	Low serum $[K^+]$
High luminal $[Na^+]$	Sodium reabsorption increases lumen electronegativity	Low luminal $[Na^+]$
High LFR	Dilutes luminal potassium; activates potassium transporters	Low LFR
High aldosterone	Activates potassium transporters	Low aldosterone

LFR, Luminal flow rate.

TABLE 21.3 Conditions and treatments affecting potassium balance in people with kidney disease.

Decrease serum $[K^+]$	Increase serum $[K^+]$
<b>Conditions</b>	
Metabolic alkalosis	Reduced glomerular filtration
Diarrhea and vomiting	Metabolic acidosis
	Diabetes mellitus, insulin resistance
	Hyporeninemic hypoaldosteronism
	Renal tubular acidosis
	Tissue catabolism (e.g., rhabdomyolysis)
<b>Treatments</b>	
Insulin and insulin-stimulating agents	RAAS inhibitors
Thiazide diuretics	K-sparing diuretics
Loop diuretics	$\beta$ -Blockers
Dialysis	Heparin

RAAS, Renin–angiotensin–aldosterone system.

regulated by potassium intake and are unaffected by conditions of insulin resistance affecting macronutrient metabolism (e.g., type 2 diabetes mellitus) [14]. Instead, in a process called *adaptation*, insulin-mediated potassium uptake by cells adjusts to match usual potassium intake, so that potassium clearance is reduced when following a low-potassium diet and increased when following a high-potassium diet [14,15]. Although the exact mechanisms involved in potassium adaptation are poorly understood, the process appears to involve an aldosterone-dependent increase in the  $Na^+-K^+$  pumps [15,16].

In the postabsorptive state, insulin concentrations return to normal, and potassium is released from cells to maintain serum potassium concentrations. In this regard, cells serve as a secondary compartment for temporary storing ingested potassium until the kidneys can excrete it. Prolonged depletion of potassium, as occurs in starvation, results in a decrease in intracellular potassium concentration, which helps drive the

rapid decrease in serum potassium concentrations seen in refeeding syndrome [17].

Catecholamines, epinephrine and norepinephrine, also affect internal potassium balance by altering  $Na^+-K^+$  pump activity.  $\beta_2$ -Adrenergic receptor binding increases  $Na^+-K^+$  pump activity, whereas  $\alpha$ -adrenergic receptor binding decreases it. This regulation is thought to help moderate potassium leak from muscle cells caused by contraction [8]. Prolonged physical activity has been shown to increase the number of  $Na^+-K^+$  pumps in muscle cells, but it is unclear whether this impacts postprandial potassium clearance, or internal potassium balance [18].

### Potassium balance in kidney disease

Patients with kidney disease experience a variety of disturbances in potassium homeostasis and balance that can lead to hypo- or hyperkalemia (Table 21.3,

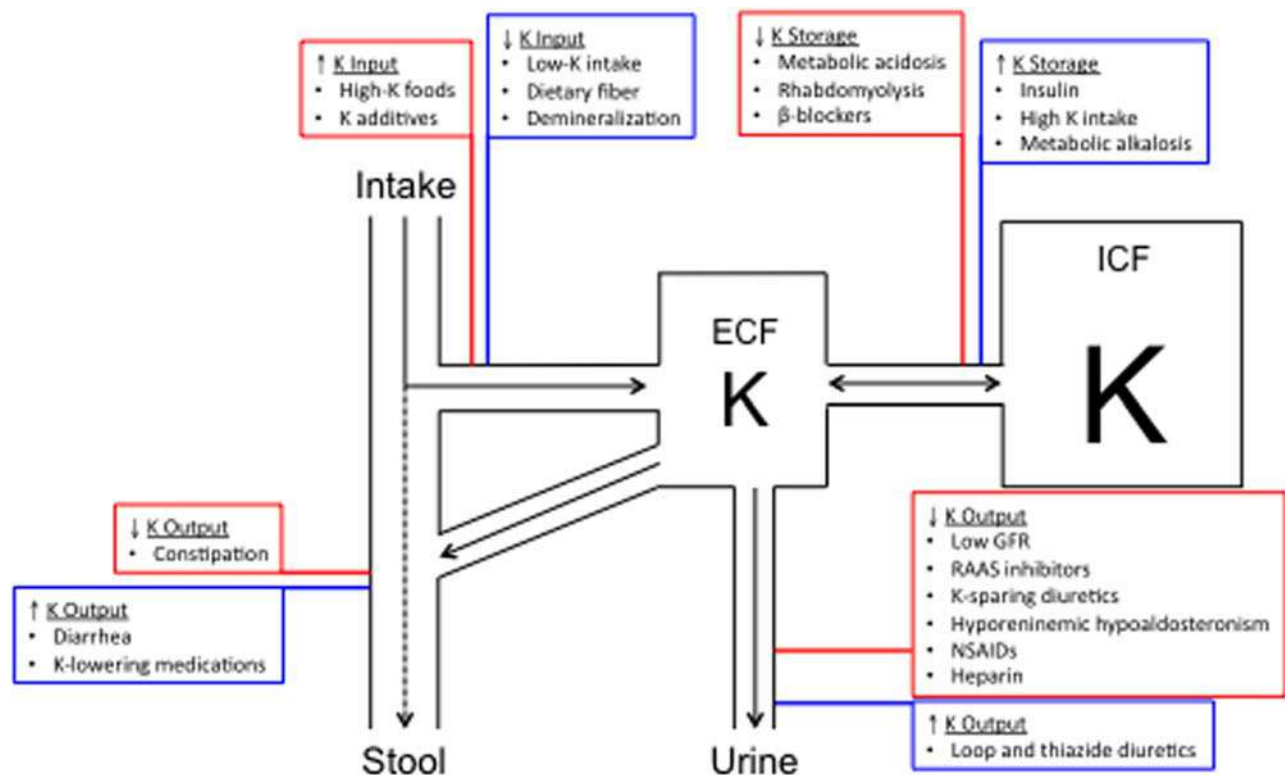

FIGURE 21.1 Factors affecting potassium balance in people with kidney disease.

Fig. 21.1). Many of these disturbances are direct or indirect results of kidney dysfunction. However, patients with kidney disease tend to have comorbidities and receive medical treatments that contribute to these disorders.

The major disturbance associated with kidney disease, which is generally the primary proximate cause of hyperkalemia, is impaired excretion of potassium by the kidneys. Although the majority of patients with kidney disease are able to maintain external potassium balance at glomerular filtration as low as 15 mL/min/1.73 m<sup>2</sup>, impaired dietary potassium tolerance resulting in postprandial hyperkalemia occurs well before this point [19]. Once glomerular filtration falls below 15 mL/min/1.73 m<sup>2</sup>, maintenance of external potassium balance shifts from the kidneys to the GI tract [20]. The extent of this shift varies considerably between individuals but may reach up to 75% of dietary potassium intake (>3000 mg/day) in some individuals [21]. The increase in potassium excretion in stool is mediated by BK channels on colonic epithelial cells that secrete potassium into the large intestine [20]. Due to the dependence on the GI tract for maintaining potassium excretion, constipation has been proposed as a modifiable risk factor for hyperkalemia in people with advanced kidney disease [22].

Even among people with kidney disease who have adequate glomerular filtration, potassium excretion in the kidneys is often hindered by factors affecting potassium secretion in the distal nephron. These factors typically involve impaired aldosterone signaling (Table 21.3, Fig. 21.1). Aldosterone secretion may be inhibited, as in hyporeninemic hypoaldosteronism secondary to diabetes mellitus or tubulointerstitial diseases, or treatment with renin–angiotensin–aldosterone system (RAAS) inhibitors such as angiotensin converting enzyme-inhibitors and angiotensin II receptor blockers [23]. Alternatively, aldosterone response may be impaired, as in type IV renal tubular acidosis, or treatment with potassium-sparing diuretics [23].

Although impaired potassium excretion is the norm in kidney disease, excess potassium excretion can also occur through several routes and lead to hypokalemia. In the kidneys, potassium-depleting diuretics used to treat hypertension and fluid overload, including thiazide and loop diuretics, increase potassium secretion by delivering more sodium and fluid to the distal nephron [24]. Potassium can also be lost via the GI tract in patients with diarrhea, which has many potential causes in this population (e.g., infections, phosphate binders) [24,25]. In end-stage kidney disease, dialysis becomes another means of removing

potassium from the body. However, it is possible to remove potassium too rapidly, or with longer dialysis treatments such as long-dwelling peritoneal dialysis and continuous renal replacement therapy, to remove too much potassium.

People with kidney disease may also have disturbances in internal potassium balance that contribute to potassium disorders. As the primary regulator of internal potassium balance,  $\text{Na}^+ - \text{K}^+$  pumps are often involved. Medications and treatments that inhibit  $\text{Na}^+ - \text{K}^+$  pumps such as  $\beta$ -blockers promote potassium efflux, whereas those that activate  $\text{Na}^+ - \text{K}^+$  pumps such as insulin promote potassium influx. Insulin release in response to dialysate glucose is thought to contribute to the high rates of hypokalemia seen in patients treated with peritoneal dialysis. Of interest, although insulin-mediated potassium clearance is normal in people with kidney disease, insulin resistance and type 2 diabetes mellitus are associated with hyperkalemia. This may be partly due to hyperglycemia, as high serum osmolality draws fluid from cells, encouraging potassium efflux through solvent drag, and raising the potassium concentration gradient.

Another major cause of abnormal internal potassium balance in people with kidney disease is metabolic acidosis. In healthy individuals the kidneys help regulate acid–base balance by modifying hydrogen ion excretion, and bicarbonate ion reabsorption. As such, mild–moderate metabolic acidosis often occurs in people with kidney disease [26]. During metabolic acidosis, particularly mineral acid metabolic acidosis, extracellular hydrogen ions are indirectly “exchanged” for intracellular potassium ions, reducing acidosis, but raising serum potassium concentrations [8].

### Assessing potassium disorders

Managing potassium disorders begins with a thorough assessment of their presentation and potential causes. The systems regulating potassium homeostasis are robust, as to prevent life-threatening shifts in

serum potassium concentrations. Consequently, potassium disorders generally result from the combination of multiple factors affecting internal and external potassium balance. As diet can modify these processes in numerous ways, an individualized, etiology-based approach is best for managing these conditions.

Serum potassium concentrations are greatly influenced by recent exposures, so dietary assessment should start with a recall of foods and beverages consumed in the day of the abnormal blood test. This recall should be paired with a diet and medical history to probe for notable changes in the previous weeks. Although hyperkalemia can sometimes be attributed to specific, high-potassium foods and beverages (Table 21.4), the amount of potassium needed to cause a clinically relevant increase in serum potassium concentrations generally exceeds that found in standard portion sizes, unless potassium clearance is severely impaired [13].

For chronic management a detailed 3-day food record should be used to evaluate usual dietary intake. Food records are preferable to dietary recalls for assessing potassium intake, as critical details of food processing and preparation can more easily be captured when recorded in real time rather than recalled from memory. Key factors to consider when analyzing food records are reflected in Table 21.5 and should expand beyond food choices to include how foods and beverages are combined in meals and distributed throughout the day.

A 24-hour urine potassium can be a useful adjunct to dietary assessment of potassium disorders. In non-dialyzed patients with preserved potassium excretion by the kidneys, urine potassium output should be approximately 70%–90% of potassium intake, providing an objective estimate of potassium exposure for assessing, monitoring, and evaluating potassium intake. Urine potassium outputs that differ substantially from expected, based on food records and serum potassium concentration, indicates a central kidney component to the disorder. Potassium wasting or impaired potassium excretion by the kidneys should be suspected if urine potassium output is  $>30 \text{ mEq/d}$  ( $>1000 \text{ mg}$ ) in hypokalemia or  $<65 \text{ mEq/d}$  ( $<2500 \text{ mg}$ ) in hyperkalemia, respectively.

TABLE 21.4 Lists of low- and high-potassium foods across food groups.

Food group	Low potassium	High potassium
Fruit	Apples, grapes, strawberries, and watermelon	Bananas, kiwi fruit, avocados, oranges, and cantaloupe
Vegetables	Cucumber, green beans, and bell peppers	Potatoes, tomatoes, squash, and spinach
Grains	Most grains	
Dairy	Cheese	Milk, soymilk, and yogurt
Protein	Eggs, beef, pork, and poultry	Nuts, seeds, legumes, and fish
Other		Coffee and tea

TABLE 21.5 General dietary strategies for preventing and managing hyperkalemia in people with kidney disease.

Strategy	Rationale and considerations
1. Eat balanced meals and snacks (i.e., $\geq 3$ food groups) with moderate portions	<ul style="list-style-type: none"> <li>Balanced meals tend to have balanced nutrient profiles</li> <li>Helps prevent overeating high-potassium foods and beverages</li> </ul>
2. Eat whole fruit and vegetables instead of juices	<ul style="list-style-type: none"> <li>Fruit and vegetable juices tend to be higher in potassium, lower in fiber, and more easily overeaten</li> </ul>
3. Limit portions of potassium-dense foods (nuts, seeds, and dried fruit)	<ul style="list-style-type: none"> <li>Easy to consume too much potassium</li> </ul>
4. Drain and rinse fluids from canned products	<ul style="list-style-type: none"> <li>Helps remove potassium</li> <li>Also removes sodium and phosphorus</li> </ul>
5. Avoid food products prepared with potassium-based food additives	<ul style="list-style-type: none"> <li>Additives can be a major source of potassium</li> <li>Additive-free products are usually available</li> </ul>
6. Use the nutrition facts panel to assess and compare products	<ul style="list-style-type: none"> <li>Helps to select lower potassium products</li> <li>Percentage of DV based on a 3500-mg potassium diet (i.e., <math>\geq 6\%</math> DV (<math>\geq 200</math> mg) = high potassium)</li> </ul>
7. Demineralize and prepare foods using wet cooking methods	<ul style="list-style-type: none"> <li>Helps remove potassium</li> <li>Also removes sodium and phosphorus</li> <li>Must discard potassium-rich cooking water</li> </ul>
8. Limit meals away from home	<ul style="list-style-type: none"> <li>Less control over food processing and preparation methods that may impact potassium content</li> <li>Portion sizes tend to be larger than appropriate</li> </ul>
9. Limit intake of high-potassium foods	<ul style="list-style-type: none"> <li>Reduce potassium intake</li> </ul>

DV, Daily value.

When analyzing urine potassium output, urine creatinine should also be measured to assess completeness of urine collection, and normalize potassium output to a parameter that is tied to energy intake [27–30]. Daily urine creatinine excretion is expected to be approximately 18 mg/kg ideal body weight (IBW) in females and 23 mg/kg IBW in males [27]. Typical urine potassium-to-creatinine ratios (K/C) range from 37.5 to 62.5 mEq/g (1.5–2.5 mg/mg). Spot urine K/C has been proposed as a less demanding approach to assessing urine potassium output. However, urinary potassium excretion rates exhibit circadian rhythms and are highly dependent of the potassium content of the previous eating occasion [8,30]. In people with kidney disease, expected urinary creatinine excretion should be adjusted downward by 0.4 mg/kg per 1.0 mg/dL of serum creatinine above normal to account for extrarenal degradation [31]. Moreover, as diet-derived creatinine (primarily from meat) contributes up to 30% of urinary creatinine output, urine potassium-to-creatinine ratios may be exaggerated in patients who limit or avoid meat.

Another useful tool for evaluating urine potassium excretion is the transtubular potassium gradient (TTKG), which examines potassium concentrations in urine and blood in relation to the osmolality ( $\text{TTKG} = (\text{urineK} \div [\text{serumK}]) \times (\text{serumOsm} \div \text{urineOsm})$ ), where K is potassium concentration and Osm is osmolality

[32]. High TTKG values ( $>2$ ) in hypokalemia suggest potassium wasting by the kidneys, whereas low TTKG values ( $<6$ ) in hyperkalemia suggest impaired potassium secretion [32]. Importantly, TTKG assessment requires that urine sodium be  $>25$  mEq/L, and urine osmolality exceeds serum osmolality [32].

### Managing hyperkalemia

Prior to treating hyperkalemia, it is important to repeat the potassium blood test to rule out pseudohyperkalemias, which are frequent and can be caused by muscle contraction from fist clenching, or activation of platelets or lysis of blood cells from a tight tourniquet or delay in analyzing the blood sample. Very high levels of white cells, as seen in hematologic malignancies, can also lead to spurious high serum potassium concentrations, in a phenomenon called reverse pseudohyperkalemia [33].

If the serum potassium concentration is severely elevated, or if hyperkalemia is accompanied by clinical abnormalities, emergent treatment may be necessary. Clinical manifestations of hyperkalemia are related to severity and duration of the disturbance and typically involve muscle weakness, which can progress to flaccid paralysis, paresthesias, delayed deep tendon reflexes,

and cardiac arrhythmias. Cardiac conduction changes associated with hyperkalemia can be assessed through an electrocardiogram (ECG) and progress from peaked T-waves, to PR prolongation, loss of P waves, QRS widening, bradycardia, and lastly a sine wave. Nonspecific ST changes can also occur. Emergent treatments for hyperkalemia typically include a combination of: (1) IV calcium to restore the transmembrane potential of contractile cells; (2) IV insulin and glucose to shift potassium intracellularly; and (3) dialysis to remove potassium.

Hyperkalemia in kidney disease is caused by excessive potassium intake, impaired potassium excretion, and/or reduced uptake and storage of potassium intracellularly. Even if the primary defect is unrelated to diet, nutrition interventions may help to address each of these problems. However, the dietary strategies are specific to the etiology and nonuniform and, therefore, should be tailored based on the nutrition assessment.

## Lowering potassium intake

Lowering dietary potassium intake is considered to be a reasonable approach for managing hyperkalemia and can be achieved in several ways. One of the main strategies is to limit or avoid high-potassium foods (Table 21.5) [34]. However, although low-potassium diet plans have been in use for more than a half century, no studies have demonstrated their efficacy for treating hyperkalemia, and observational studies

have failed to find a strong association between dietary potassium intake and serum potassium concentrations in hemodialysis patients [22]. This approach has many pitfalls and may exacerbate problems related to potassium excretion and distribution in the body, which could increase serum potassium concentrations [22,35].

As shown in Fig. 21.2, restricting high-potassium foods has the greatest potential to lower potassium intake while maintaining dietary balance within the fruit, vegetable, and protein food groups, where the potassium content is relatively high, and highly variable. Table 21.4 provides lists of low- and high-potassium foods for reference. Such lists can help to inform nutrition assessment and guide patient education. However, food lists should only be used in conjunction with medical nutrition therapy by a nutrition expert such as a registered dietitian.

One of the main flaws of the food list approach to dietary counseling is that food processing and preparation methods can add, concentrate, dilute, or remove potassium from foods, dramatically altering their potassium content (Fig. 21.3). In general, processes that add or concentrate potassium will increase the risk of hyperkalemia, and processes that dilute or remove potassium will decrease the risk of hyperkalemia.

## Added potassium

Added potassium is primarily in the form of potassium salts in processed foods such as potassium

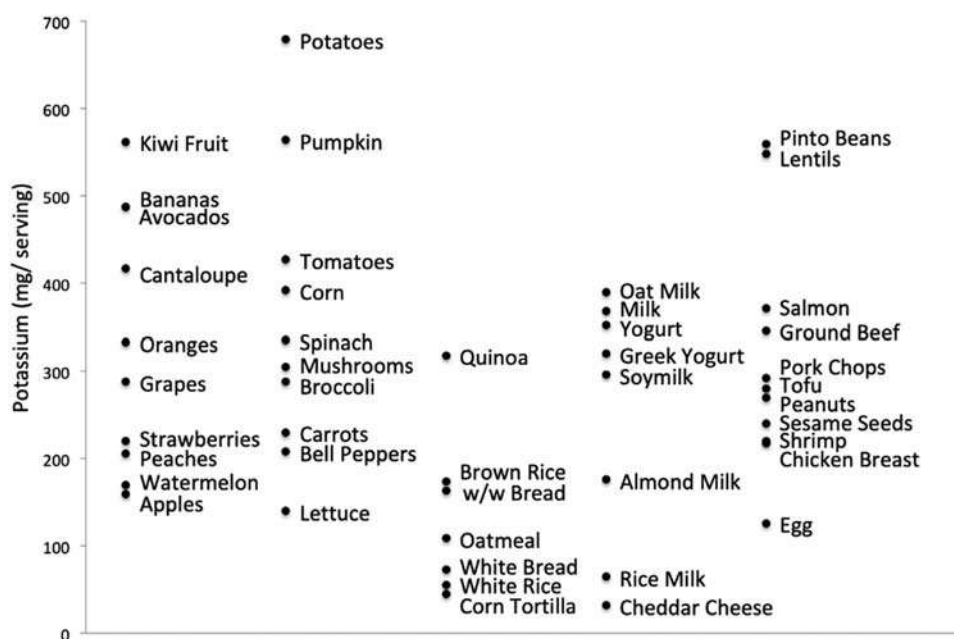

FIGURE 21.2 Potassium content of foods across food groups.

FIGURE 21.3 Effect of food processing and preparation of the potassium content of apple products.

chloride, potassium citrate, and potassium lactate. Although data on potassium additives is sparse, analyses of processed animal products suggest that the amount of added potassium is highly variable and can be substantial [36–38]. Indeed, animal products containing potassium additives have been found to contain approximately 150 mg more potassium per 100 g serving, reaching +600 mg potassium/serving for some products [36].

Potassium chloride deserves particular attention for people with kidney disease following a low-sodium diet because of its function as a substitute for table salt. Like sodium chloride (table salt), potassium chloride has a salty taste, making it widely used in low-sodium products. Potassium chloride-based salt substitute products are also available for use at home, and their use has been linked to several cases of hyperkalemia in people with kidney disease [39].

Potassium additives can usually be identified using the ingredients list, and additive-free alternatives are generally available. Most food products containing potassium-based food additives will contain a nutrition facts panel indicating the overall potassium content of the product. The amount of potassium on the nutrition facts panel is based on a 3500 mg potassium, 2000-cal diet. Foods containing  $\geq 6\%$  of the daily value for potassium ( $\geq 200$  mg/serving) are typically considered to be high-potassium. However, serving sizes on food products can differ substantially from the portion consumed, and mislabeling of nutrients by manufacturers is relatively common [40]. Consequently, patients with hyperkalemia should be advised to avoid any processed foods prepared with potassium additives.

### Concentrating and diluting potassium

Dehydrating and juicing can increase the amount of potassium in a standard portion of food. Because the amount of food consumed in a meal is primarily determined by its weight/volume, foods with high per portion potassium are more likely to contribute to postprandial hyperkalemia. For this reason, dried fruits are generally regarded as high-potassium foods, even if their hydrated counterparts are low in potassium (e.g., grapes and raisins) [34]. Similarly, juices tend to be consumed in amounts that exceed the usual intakes of their fruit and vegetable source, and excessive consumption of juice from even low-potassium fruit such as apple juice has been linked to hyperkalemic episodes [39]. Consequently, people with kidney disease should rarely consume dried fruit, and fruit and vegetable juices, and always in moderation.

In contrast to the amount of potassium in a meal, which depends on portion size, overall dietary potassium intake is primarily determined by potassium density, or the amount of potassium per calorie. Food processing and preparation can alter the potassium density of foods substantially by adding or removing energy-containing compounds. Factors that add calories such as adding sugars and frying foods in fat tend to reduce (dilute) the potassium density of foods, whereas factors that remove calories such as skimming and trimming fat tend to raise (concentrate) the potassium density of foods. For example, fat-free plain yogurt can contain as much as three times more potassium per calorie as sweetened high-fat alternatives. Importantly, adding empty calories to food reduces the intake of beneficial nutrients and may exacerbate

other diet-related conditions (e.g., added sugar and hyperglycemia). As a result, this approach is not recommended for managing hyperkalemia.

### Removing potassium

When foods are soaked and/or cooked with water, potassium diffuses from the food into the water, which can then be discarded (called “demineralization”) [41]. The amount of potassium removed depends on the duration of soaking, temperature of the water, and surface area of the food. As a general rule, 30–60 minutes of soaking in hot water (100°F) is sufficient to cut the potassium content of foods in about half [41]. Demineralization has the added benefit of removing sodium and phosphorus from foods, but can also result in the loss of other heat-labile and water-soluble nutrients, and affects the palatability of certain foods [41]. Therefore people with kidney disease should primarily use demineralization on high-potassium foods that prepare well with wet cooking methods such as starchy vegetables, meat products, and legumes.

### Increasing potassium excretion

The primary defects in potassium excretion in kidney disease occur at the kidney and are largely consequences of kidney disease pathogenesis or treatment that are not readily modified by diet. However, in advanced CKD, the GI tract becomes an increasingly important route of potassium excretion. Furthermore, constipation is relatively common [42], and stool outflow is the primary determinant of potassium excretion by the GI tract [20].

Fiber is the main dietary factor affecting stool output, and together with fluids and physical activity, are the chief lifestyle recommendations for preventing and treating constipation [43]. In healthy individuals, dietary fiber has been shown to increase potassium excretion in stool as much as threefold [5]. The majority of fiber in the diet comes from whole plant foods, including fruit, vegetables, whole grains, nuts, seed, and legumes, although fiber-based food additives and fiber supplements can also be major sources of fiber intake. As many dietary sources of fiber are also high in potassium, the benefits of increasing potassium excretion must be weighed against the potential for increasing potassium intake. However, patients with hyperkalemia, particularly those who report symptoms of constipation, should be encouraged to consume whole plant foods and engage in moderate intensity physical activity, as appropriate.

### Increasing potassium uptake and storage in cells

Uptake of potassium into cells is critical for preventing postprandial hyperkalemia in people with kidney disease. As discussed previously, this process is mediated by the action of insulin on  $\text{Na}^+ - \text{K}^+$  pump activity. While this pathway is specific to potassium, macronutrients are needed to trigger insulin secretion. Consequently, patients with hyperkalemia should consume balanced meals, ideally prepared from scratch, as they are more likely to contain an appropriate balance of potassium and necessary macronutrients.

Postprandial potassium clearance is also highly dependent on usual potassium intake [15,16]. Although limiting potassium intake is recommended for managing hyperkalemia, strict adherence to a low-potassium diet reduces dietary potassium tolerance through adaptation, priming patients to postprandial hyperkalemia in the event that a high-potassium meal is consumed [15,16]. For this reason, patients following a low-potassium diet should be weary of processed food and meals consumed away from home, which may contain hidden sources of potassium (e.g., additives).

One of the main diet-related complications affecting the distribution of potassium in the body is metabolic acidosis [8]. Diet contributes up to half of the total acid load that is excreted by the kidneys in healthy individuals [44]. Dietary acid load is primarily generated from metabolism of basic and sulfur-containing amino acids into hydrochloric and sulfuric acid, respectively, and phosphate-containing salts (e.g., phosphoric acid) [44]. Acid in the body can be neutralized by base-forming organic acids, which are bound to minerals, especially potassium (e.g., potassium citrate), in fruits and vegetables [44]. Indeed, protein and potassium are key variables in equations for estimating dietary acid load [44]:

*Net endogenous acid load* (mEq/d) =  $(54.5 \times \text{protein (g/d)}) / \text{potassium (mEq/d)} - 10.2$

*Potential renal acid load* (mEq/d) =  $(0.49 \times \text{protein (g/d)}) + (0.037 \times \text{phosphorus (mg/d)}) - (0.021 \times \text{potassium (mg/d)}) - (0.026 \times \text{magnesium (mg/d)}) - (0.013 \times \text{calcium (mg/d)})$

An alkaline diet, low in acid-forming animal-based protein foods and high in base-forming fruits and vegetables, can be used to treat metabolic acidosis (total  $\text{CO}_2 < 25$  mEq/L) [45,46] and may have additional health benefits in people with kidney disease [46,47]. However, this approach has not been tested in patients with hyperkalemia and must be weighed against efforts to lower potassium intake [22].

Diabetes mellitus is another common cooccurring condition in people with kidney disease, which may contribute to hyperkalemia in several ways. For patients with  $\beta$ -cell failure requiring exogenous insulin

or insulin-stimulating agents, balancing potassium intake with carbohydrates and medications is crucial for maintaining serum potassium and glucose homeostasis. As poor glycemic control can lead to conditions that increase serum potassium concentrations (e.g., hyporeninemic hypoaldosteronism, hyperglycemia, and ketoacidosis), dietary guidelines for managing diabetes mellitus should be followed in these patients.

## Nondietary approaches to hyperkalemia

Nondietary strategies may be equally or more effective in managing hyperkalemia and should be explored:

1. May be possible to address iatrogenic causes by adjusting dialysis and medications regimens (Table 21.3, Fig. 21.1).
  - a. Medications for RAAS inhibition.
  - b.  $\beta$ -Blockers, heparin, and NSAIDs.
2. May be able to address underlining etiology.
  - a. Treat AKI, if possible, which should return potassium to normal.
  - b. Metabolic acidosis and constipation may be treated with medications.
3. May be able to provide treatments to increase potassium excretion.
  - a. Increase dialysis or improve adherence.
  - b. Potassium binders (discussed further next).
  - c. Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics can all contribute to kaliuresis. In patients with eGFR of less than 30 mL/min/1.73 m<sup>2</sup>, loop diuretics are the preferred agent.

Currently, potassium binders are used both in acute and chronic hyperkalemia management. In acute hyperkalemia, binders are used in conjunction with emergent treatment strategies for hyperkalemia. In chronic hyperkalemia, binders are also used to maintain normokalemia from underlying disease, and increasingly to continue medications that can cause hyperkalemia, but have other beneficial effects (usually RAAS inhibitors) [48].

In 1958 the FDA approved the first potassium binder for the treatment of hyperkalemia. Sodium polystyrene sulfonate (SPS) (brand name Kayexalate) is an exchange resin where sodium and hydrogen ions are exchanged for other cations in the colon [49]. It is available as a powder, and in a mixture with sorbitol (20 g of sorbitol per 15 g of SPS). There are also 1500 mg of sodium per 15 g dose. The exchange function of this medication is not specific to potassium. Magnesium and calcium can also be bound. Each 1 g of SPS is thought to bind 1 mEq of potassium [50]. For decades, this was the only oral exchange resin available and widely used for hyperkalemia. Its use has

been called into question, as at the time it was approved, the FDA did not require a demonstration of efficacy for approval, and safety concerns over bowel necrosis and other reported GI side effects [51]. In 2009 the FDA used a warning to regarding these side effects and to avoid concomitant administration of sorbitol [49]. Despite this the combination is still widely available. The large stool volume from the sorbitol is thought to be a mechanism for its potassium lowering [52,53]. Two randomized clinical trials using SPS have been complete. In one trial of CKD patients the mean potassium concentration decreased for  $5.8 \pm 0.6$ – $4.3 \pm 0.5$  mEq/L by day 3 with 5 g thrice daily dosing. Magnesium levels were not measured [51]. In the other study of 33 CKD patients, SPS did normalize serum potassium levels in 73% of the patients taking it for 7 days. Hypomagnesemia was observed in 31.3% of patients, and hypocalcaemia in 18.8% of treated patients [54]. Retrospective data have shown that a single 30-g dose decreases serum potassium by a median of 0.8 mEq/L in CKD stages 4 and 5 [55]. These small studies did demonstrate efficacy, but the variable time to normokalemia, and other reports of adverse events, do challenge its places as standard therapy for acute and chronic hyperkalemia. The concerns over sodium load and GI toxicity continue to limit the use of this drug.

Patiromer (brand name Veltassa) was the next non-absorbed binder approved. It exchanges calcium for potassium or other cations in the colon, where potassium concentrations in the gut are highest [56]. The use of calcium rather than sodium to exchange for potassium ameliorates the risk of sodium loading seen with other potassium binders [56]. Patiromer was well tolerated in clinical trials of CKD patients on RAAS blockers [57]. In the Amethyst-DT clinical trial of CKD patients with diabetic kidney disease, the range of potassium decrease was dose-dependent and ranged from a mean reduction of 0.35 to 0.97 mEq/L, depending on the dose. Constipation and hypomagnesemia requiring repletion are common reported side effects [57], although increases in urinary calcium excretion, and decreases in urinary phosphorus and sodium excretion have also been noted. Patiromer also appeared to be generally well tolerated in heart failure patients in that trial [58].

Sodium zirconium cyclosilicate (brand name Lokelma) is a nonabsorbed compound that binds preferentially exchanges hydrogen and sodium for potassium and ammonium in the gut. The compound is highly selective for potassium compared to magnesium [59]. Binding can occur throughout the gut, making it attractive for consideration as both an acute and chronic therapy [60]. Each 5-g dose (the lowest dose) of Lokelma contains about 400 mg of sodium, and the recommended doses range from 5 g daily to 10 g thrice daily depending on the clinical scenario. In one

clinical trial, potassium lowering occurred in a dose-dependent fashion up to an average of 0.7 mEq/L in the 10 g thrice daily dose at 48 hours [61]. Edema has been reported in patients receiving higher doses [62].

### Managing hypokalemia

Although decline in glomerular filtration from loss of functional nephrons promotes hyperkalemia, kidney disease is also associated with hypokalemia, which can be just as dangerous. Similar to hyperkalemia, consequences of hypokalemia are principally caused by disturbed action potentials in neurons and muscle cells. Symptoms and signs of hypokalemia usually manifest once serum potassium fall below 3.0 mEq/L and include muscle cramping, weakness and/or paralysis, constipation, and torsades de pointe [63]. Severe hypokalemia can result in rhabdomyolysis and heart failure, and if prolonged, can exacerbate kidney disease, as seen in interstitial nephritis and nephrogenic diabetes insipidus [63]. ECG changes seem with hypokalemia include U-waves, T-wave flattening, and ST segment changes [63].

Treatment for hypokalemia is directed toward repleting potassium stores, if necessary, and if possible, addressing the underlying cause(s) of hypokalemia. Potassium repletion is usually achieved with oral potassium chloride (KCl; brand name Slow-K). However, if hypokalemia is severe ( $<2.5$  mEq/L), or if it associated with a GI conditions that preclude oral repletion, or clinical symptoms and signs of hypokalemia, KCl should be provided intravenously with great caution regarding vascular access and flow rate. To prevent side effects and rebound hyperkalemia, potassium repletion should not exceed 20 mEq of KCl (approximately 800 mg) of potassium at one time. In addition, before attempting to replete potassium, it is important to assess for and address concurrent hypomagnesemia, which occurs in nearly half of cases and can lead to potassium-refractory hypokalemia [64].

Hypokalemia in kidney disease is caused by inadequate potassium intake, excessive potassium losses, and/or increased uptake and storage of potassium intracellularly (Fig. 21.1). Because potassium is ubiquitous in the diet (Fig. 21.2), inadequate potassium intake is rarely caused by consuming a low-potassium diet but may occur secondary to malnutrition. To avoid refeeding syndrome, malnourished patients should increase energy intake slowly (200–300 kcal/day), and closely monitor electrolytes for abnormalities. Normal serum potassium concentrations are not required before treating malnutrition. However, increasing energy intake will trigger insulin-mediated potassium uptake by cells, so patients with hypokalemia should receive prophylactic potassium when treated for malnutrition.

Potassium losses in people with kidney disease can occur via multiple routes, primarily the kidneys, dialysis, and GI tract. Excessive potassium losses causing hypokalemia often requires supplemental potassium to replete body stores and changes to medication and dialysis to treat. Although diet is unlikely to be the primary cause of vomiting and diarrhea in people with kidney disease, it may have a role in managing these conditions. Importantly, as vomiting and diarrhea are broad, nonspecific symptoms with varied pathophysiologies, dietary intervention should be tailored based on the patient's response to food.

Patients with chronic vomiting should try limiting potentially nauseating or offending foods (e.g., foods with strong odors), and consuming small/frequent, bland meals [65]. In kidney disease, nausea and vomiting may be caused by uremia, particularly as blood urea nitrogen levels rise above 160 mg/dL. Such patients may benefit from limiting protein intake [35,66]. Another potential cause of vomiting in this population is gastroparesis [65]. In these patients, limiting dietary fat and fiber intake and consuming liquid nutrition sources can speed gastric emptying. However, these modifications are likely to increase dietary glycemic index, which could actually worsen gastroparesis in people with diabetes, if glycemia is not controlled.

Patients with chronic diarrhea should try limiting foods containing nutrients that tend to be poorly absorbed, osmotically active, and/or highly fermented in the GI tract. Some notable examples include fats, soluble fibers, lactose, and fructose. The low-FODMAP diet (Fermentable, Oligo-, Di-, Mono-saccharides And Polyols) has been shown to reduce diarrhea symptoms in patients with irritable bowel syndrome and may be beneficial in some patients. If diarrhea is severe and intractable, a nil per os or empirical elimination diet may be trialed temporarily to help identify dietary culprits. Hidden drugs consumption such as diuretics and laxatives should also be searched for, as they can lead to long-term hypokalemic status and secondary tubulointerstitial disease and kidney failure.

### Case study—hyperkalemia in chronic kidney disease

Referral: New-onset hyperkalemia

History of present illness: 61-year-old diabetic male with no acute complaints. Mr. S reports complete adherence to prescribed medications, which have not changed since previous visit with normal serum potassium concentration (4.8 mEq/L). He was referred by his doctor for hyperkalemia on two subsequent laboratory tests. He reports that he has not self-monitored his blood sugars for many years.

Review of systems is negative except for occasional constipation. He has two bowel movements per week with difficulty.

Past medical history: Stage G4A3 CKD (12 years), T2D (18 years), HTN (18 years)

Medications/supplements: Ramipril (5 mg), Losartan (25 mg), insulin withheld for fasting blood tests.

Sociodemographics: non-Hispanic white male, lives with spouse, employed full-time (attorney), income meets needs.

Physical exam findings: Wt: 85 kg, Ht: 5'7", BMI: 29.4 kg/m<sup>2</sup>, WC: 42", BP: 131/83 mmHg, HR: 84 bpm. Mr. S weight has been stable. His BMI is classified as overweight (29.4 kg/m<sup>2</sup>), and his waist circumference was 42", indicating central adiposity.

General: well appearing, well-nourished male

Heart: normal rhythm

Lungs: no crackles/rales

Extremities: 1+ bilateral pitting edema

Diet history: Dietary recall indicates that Mr. S was fasted during blood testing, except for his usual mug of plain, black coffee. His most recent eating occasion was a bowl of low-sodium microwave popcorn, which he consumes most evenings while watching TV. Mr. S reports that he has been trying to incorporate more kidney-friendly foods since his checkup in July. In particular, he has replaced his usual cola with cranberry juice and started eating cauliflower with ranch dressing as a snack. Three-day food records indicate that Mr. S consumes a typical Western diet, high in grains and animal-based protein foods, and low in fruit, vegetables, and dairy products. Approximately half of his meals are consumed away from home and homemade meals (prepared by Mr. S) tend to be processed or ultraprocessed rather than unprocessed or minimally processed. His juice consumption is around three cups per day (contain 250–750 mg potassium/cup) and makes up the majority of his fruit and vegetable intake.

Laboratory report:

	10.18.19	10.20.19	10.21.19	Reference

Questions:

1. Is potassium excretion impaired?  
Yes, urinary potassium output is low in relation to reported intake, as well as creatinine and urea nitrogen excretion. The TTKG is also low (3.9). This may be caused by RAAS inhibitors and/or hyporeninemic hypoaldosteronism secondary to uncontrolled diabetes mellitus. Stool potassium output was not measured but may be limited by constipation.
2. What short-term factors may have contributed to hyperkalemia?
  - a. Coffee is a relatively high-potassium beverage and is low in insulin-stimulating nutrients.
  - b. Exogenous insulin was withheld during fasting blood tests to prevent hypoglycemia, but prolonged fasting and hypoinsulinemia can contribute to hyperkalemia.
3. How should potassium intake be evaluated and monitored in this patient?
  - a. 3-day food record with targeted diet history based on intervention.
  - b. 24-hour urinary potassium and creatinine.
4. What pharmacologic interventions are available for the management of this patient?

- a. Diuretics can increase kaliuresis.
  - b. Addition of alkalinizing agent to promote kaliuresis, and intracellular shift of potassium.
  - c. Stop dual RAAS inhibition, which is known to be associated with an increased risk of hyperkalemia.
  - d. Laxatives to treat his constipation.
  - e. Potassium-binding agents may be considered if other changes are inadequate, or current RAAS inhibiting medications cannot be decreased.
5. What diet-related problems may be contributing to hyperkalemia in Mr. S, and why?
- a. Consuming meals away from home. Unable to control and difficult to assess food processing and preparation factors that may increase potassium intake (e.g., additives). Meals and portion sizes are often unbalanced.
  - b. Excessive consumption of potassium-rich beverages, which are concentrated sources of potassium; some without adequate amounts of insulin-stimulating macronutrients (e.g., black coffee). Lack dietary fiber.
  - c. Low-dietary fiber intake. May contribute to infrequent bowel movements, reducing potassium excretion in stool.
  - d. Intake of high-potassium foods (e.g., fruit juice).
  - e. Excessive dietary acid load. May contribute to metabolic acidosis, reducing potassium uptake by cells.

## Magnesium and kidney disease

Mugurel Apetrii<sup>1</sup>, Adrian Covic<sup>1</sup> and Ziad A. Massy<sup>2,3</sup>

<sup>1</sup>Nephrology Department, “Grigore T Popa”, University of Medicine and Pharmacy, Iasi, Romania <sup>2</sup>Division of Nephrology, Ambroise Paré Hospital, APHP, Paris, France <sup>3</sup>Inserm U1018, UVSQ, Université Paris-Saclay, Paris, France

### Introduction

Magnesium (Mg) is the fourth most abundant cation in the body and the second most important intracellular cation [1]. It is an essential cation for multiple processes in the body playing an important role in neuromuscular processes, as a cofactor in multiple enzymatic reactions, in mineral bone metabolism, adenosine triphosphate metabolism, neurotransmitter release, and in the regulation of vascular tone, heart rhythm, and platelet-activated thrombosis [2,3].

Chronic kidney disease (CKD) affects approximately 13% of the general population [4] and is associated with the increased risk of cardiovascular disease (CVD) because of both traditional and nontraditional CVD risk factors [5]. Epidemiological studies have found positive correlations between higher levels of Mg and improved survival among patients suffering from CKD and end-stage renal disease (ESRD) [6,7], while hypomagnesemia is significantly associated with cardiovascular and all-cause mortality in patients with CKD and ESRD [8]. However, data are sparse regarding evidence-providing, prospective, randomized, controlled trials investigating the impact of Mg supplementation upon the reduction of these cardiovascular risks and improved CV outcome [9].

### Serum magnesium in chronic kidney disease

Magnesium is predominantly an intracellular cation, approximately one-third of the total Mg in the body being present in the intracellular space, a small amount (2%) in the extracellular space, the remainder (56%) in

bone [3]. Less than 1% of the total body Mg is present in the intravascular compartment [10]. Normal serum Mg concentrations range from 0.7 to 1.1 mmol/L (1.4–2.0 mEq/L or 1.7–2.4 mg/dL) and can be categorized into three fractions: ionized (55%–70%), protein-bound (20%–30%), and complexed with anions such as phosphate, bicarbonate, citrate, or sulfate (5%–15%).

As with other electrolytes, Mg homeostasis depends on the balance between gastrointestinal absorption and kidney excretion and changes in intake being balanced by changes in renal Mg reabsorption, principally in the loop of Henle and the distal tubule. The kidney provides the most sensitive control for Mg balance and although the renal handling of Mg is highly adaptable, this ability deteriorates when renal function declines significantly.

The average daily Mg intake is 360 mg (15 mmol), approximately one-third being absorbed, principally in the small bowel through both an active and passive diffusion. The renal handling of Mg depends mainly on its plasma concentration, calcium levels (hypercalcemia inhibits Mg reabsorption), and several other factors like metabolic alkalosis that stimulates reabsorption in contrast with metabolic acidosis, hypokalemia, and phosphate depletion which inhibit Mg reabsorption. Diuretics also affect Mg handling, thiazide diuretics being associated with Mg wasting, and amiloride with distal tubular reabsorption of Mg.

Contrary to other ions that are maintained within a narrow range by the action of several hormones, Mg is treated differently: there are no hormones that have a substantial role in regulating urinary Mg excretion, and bone, the principal reservoir of Mg, does not readily exchange with circulating Mg. Thus in the setting of negative Mg balance, the plasma Mg concentration falls rapidly with negative Mg balance, leading to a

marked reduction in Mg excretion. Conversely, there is no protection against hypermagnesemia with the loss of renal function. In this setting, continued intake leads to Mg retention that is predominant in the extracellular fluid.

Modulation of serum magnesium in chronic kidney disease patients

Magnesium dosing

In moderate CKD the increase in the fractional excretion of Mg largely compensates for the loss of glomerular filtration rate (GFR) to maintain normal serum Mg levels. However, in more advanced CKD [as estimated GFR (eGFR) falls <30 mL/min], this compensatory mechanism becomes inadequate such that overt hypermagnesemia might occur in patients with eGFR <10 mL/min. However, observational data do not support this hypothesis, in the real life, both CKD and ESRD patients have normal serum levels of Mg and sometimes even low serum Mg concentration [11]. This is due to the intake of Mg coupled with other dietary intake which might interfere with intestinal absorption and dialysate Mg concentration or some drugs such as thiazide diuretics, proton-pump inhibitors (PPIs), cisplatin, aminoglycoside antibiotics, and calcineurin inhibitors. Moreover, recent evidence highlights the role of proteinuria in inducing renal Mg wasting tubular injuries, which explains the high prevalence of HypoMg in CKD [12].

Alterations in circulating serum Mg concentrations are offset by intracellular stores, so that a negative daily Mg balance may not manifest with lower Mg concentrations. Intracellular Mg depletion and normal serum Mg concentrations may coexist, and total Mg

deficiency might not manifest until cellular stores are exhausted. Therefore using serum Mg levels to diagnose Mg deficiency may not be very accurate.

Since 99% of Mg is intracellular, Mg concentrations in body tissues or blood cells (i.e., erythrocytes) were thought to be a better marker for Mg deficit or overload. Erythrocyte Mg concentration was found to be higher in CKD patients than healthy volunteers, although an inverse correlation between Mg concentration of erythrocytes and hematocrit was found, suggesting that anemia, rather than renal failure, might explain the high concentration of Mg in erythrocytes [13,14].

Drugs associated with hypo or hypermagnesemia

Certain drugs widely used in patients with CKD can decrease gastrointestinal ingestion or kidney excretion of Mg and potentially cause hypomagnesemia, while other Mg-containing drugs (e.g., certain laxatives and antacids) may induce hypermagnesemia, particularly in those with impaired renal function [15] (see Table 22.1).

PPIs are potent blockers of gastric acid secretion, used by millions of patients suffering from gastric acid-related complaints; although in general they have a good safety profile, their long-term use is associated with decreasing the Mg intestinal absorption via an unknown mechanism. This might be related to the decreased function of TRPM 6/7 channels, the site of active intestinal Mg transport [16]. This channel is particularly important in times of low Mg intake and might explain why malnutrition is a specific risk factor for PPIs-associated hypomagnesemia.

Cation exchange polymer has been long time used as a treatment for hyperkalemia, particularly in those with CKD. Hypomagnesemia does not typically occur with sodium polystyrene sulfonate exposure, but newer

TABLE 22.1 Drugs interference with serum Mg level.

Drugs associated with hypoMg	Drug associated with hyperMg
Proton-pump inhibitors	Laxatives (Mg hydroxide or Mg sulfate) and enemas
Cation exchange polymer (stool softeners—docusate, stimulants—senna, osmotic laxatives, and patiromer)	Mg-containing phosphate binders
Loop and thiazide diuretics	SGLT2 inhibitors—canagliflozin, empagliflozin, and dapagliflozin
Antimicrobials (including antifungals and antivirals)—aminoglycosides, amphotericin B, and foscarnet	
Calcimimetics	
Immunosuppressives—cyclosporine, tacrolimus	
Chemotherapy—cisplatin, carboplatin, monoclonal antibodies blocking the epidermal growth factor receptor like cetuximab and panitumumab	

SGLT-2, Sodium–glucose cotransporter 2.

agent, patiomer, was associated with significantly more cases of hypomagnesemia than placebo in a recent multicenter randomized controlled trial in CKD patients [17].

*Loop and thiazide diuretics* inhibit Mg reabsorption in the loop of Henle and distal convoluted tubules (DCT), respectively. However, the effect of loop diuretics on Mg concentrations is generally mild. In the clinical setting of diuretic-induced hypomagnesemia, when continued diuretic use is warranted, the addition of potassium sparing diuretics such as amiloride might be useful. These drugs may decrease Mg wasting by increasing reabsorption in the distal nephron [18].

Many other drugs like *antimicrobials*, *calcimimetics*, *immunosuppressives*, or *chemotherapy* may induce hypomagnesemia via a direct tubular toxic effect or decreased expression of TRPM6 in the DCT, respectively.

Conversely, others drugs like *laxatives*, *enemas*, *phosphate binders*, or even *sodium–glucose cotransporter 2 (SGLT-2) inhibitors* are associated with hypermagnesemia in the setting of impaired renal function. Magnesium, by increasing the intestinal osmotic gradient and consequent water movement, is an important component of many laxatives and enemas; the risk of hypermagnesemia is directly proportional to the amount of Mg ingestion and the kidney excretory capacity. This may become clinically relevant especially in setting of advanced CKD (stages 4 and 5), Mg-free containing preparation are preferred.

*Magnesium-containing phosphate binders* might induce hypermagnesemia, but this is generally well tolerated without any toxic effect [19]. Sevelamer hydrochloride, a calcium-free intestinally nonabsorbed polymer, is also associated with hypermagnesemia through its capacity of binding biliary salts thereby increasing free Mg for intestinal absorption [20].

*SGLT-2 inhibitors* are a new class of antidiabetic medications indicated for treatment for type 2 diabetes mellitus because they inhibit glucose reabsorption in the proximal tubule, thereby increasing urinary glucose excretion and reducing plasma glucose concentrations. A large body of new evidence underlines a positive effect for these agents in decreasing the cardiovascular risk and even the risk of CKD progression [21]. SGLT2 inhibitors have been associated with increasing serum Mg, through an improved insulin sensitivity, increase in plasma glucagon leading to increase in Mg reabsorption at the DCT, osmotic diuresis from glycosuria leading to electrolyte abnormalities, and/or SGLT2 inhibitor effect on TRPM6/TRPM7 channels in the DCT. The incidence of hypermagnesemia has not been well defined in studies because severe CKD patients were excluded from these studies. Currently, the use of SGLT2 inhibitors is restricted to patients with  $\text{eGFR} > 45 \text{ mL/min/1.73 m}^2$ .

## Magnesium and outcomes

### Magnesium and vascular calcification in chronic kidney disease patients

CVD is the leading cause of death in the CKD population, the high prevalence of vascular calcification (VC) having a significant role to this cardiovascular risk [22]. The pathogenesis of VCs in CKD patients is complex, but it appears that Mg plays an important role in preventing VC in these patients. These positive effects are thought to be mediated by an antagonistic effect of Mg on the procalcifying milieu in CKD [10]. Thus in vitro data suggest that adding or increasing Mg may prevent calcification induced by calcium and high phosphate by the upregulation of factors that inhibit calcification and the downregulation of factors that promote calcification [23,24]. Furthermore, in other model of experimental uremia, Mg supplementation alone reduces ectopic calcification severity [25]. These experimental data were also confirmed in humans in small clinical trial of Mg supplementation in predialysis and ESRD patients [26]. Although it is well known that the uremic toxin indoxyl sulfate aggravates VC, administration of the oral carbon adsorbent AST-120 did not influenced the progression of VC, while supplementation with Mg did so [25]. Therefore Mg supplementation could potentially be a therapeutic option to attenuate the progression of VC in CKD. Because serum Mg depends on its renal excretion, Mg therapy might be associated with hypermagnesemia in CKD patients. This hypothesis was not confirmed by a small recent randomized controlled trial in which oral Mg supplementation in subjects with CKD stages 3 and 4 was safe and well tolerated. Although both serum and urine Mg increased, this was not associated with increased intracellular Mg or significant serious adverse events related to the study medication [27].

A deficiency in Mg promotes hydroxyapatite formation and calcification of vascular smooth muscle cells [28]. On the other hand, chronic hypermagnesemia in dialysis patients plays an important role in the genesis of adynamic bone disease, although the exact mechanisms are not yet clear [29,30]. Additionally, Mg prevents the maturation of calciprotein particles and, thus, VC progression—transformation from soluble nanoparticles containing amorphous calcium phosphate into elongated particles containing crystalline hydroxyapatite.

### Magnesium and mortality in chronic kidney disease

In recent years, many observational studies have shown that Mg concentrations are positively associated with better survival in CKD cohorts and more importantly, this association seems to be robust and remained

after adjusting for multiple covariables, including comorbidity and surrogates of nutritional status (body mass index, albumin) [6,31,32].

Several potential mechanisms explaining the role of Mg in clinical outcomes in CKD patient were postulated. First, lower serum Mg concentration has been associated with increased risk for sudden death in CKD patients mainly related to cardiac dysrhythmia [31]. Hypomagnesemia is associated with electrographic disturbances, including tachyarrhythmia and prolonged duration of repolarization, because it is well known that Mg is involved in the molecular mechanisms of cardiac excitation [33]. Mg has a role in establishing, and the maintenance of, the resting transmembrane potential being a critical cofactor for the Na/K-ATPase. Thus hypomagnesemia leads to a decreased activity of Na/K-ATPase which lowers the intracellular potassium concentration promoting hyperexcitability through a low resting membrane potential more close to the threshold potential. Mg also regulates the function of multiple other ion channels (notably sodium and calcium channels) during the course of the action potential as well. As a consequence, Mg depletion may prolong the depolarization time and make the heart more vulnerable to arrhythmia.

Moreover, in patients with CKD, a lower serum Mg is associated with a higher left ventricular mass index, thus providing another possible causal explanation of the association between serum Mg and cardiovascular mortality in CKD patients [34].

And finally, Mg also affects blood pressure and endothelial function. Higher serum Mg concentration is associated with improved endothelial dysfunction in patients with CKD, demonstrated by increased flow-mediated dilation, and in the general population serum magnesium is inversely associated with incident hypertension [6,35]. Despite the accumulating literature data suggesting the association between higher Mg level and a more favorable outcome, the effect of Mg administration on mortality in CKD patients has never been investigated as a primary end point. Therefore randomized, controlled trials designed to address the role of Mg in survival are required to preclude stronger conclusion.

### Nutritional aspects

Daily requirement for Mg in adults is estimated to be 8–16 mmol (200–400 mg), values close to the recommended daily allowance (420 mg/day for adult males and 320 mg/day for adult females) [36]. While Mg is widely distributed in most human foods, it is important to note that only 30% of ingested Mg is absorbed across the intestine, utilizing both paracellular and active

transport mechanisms. While 35% of absorbed Mg complexes to either albumin or other anions, the remaining circulates unbound, fluxing between the serum and the much larger intracellular depot. It is also important to note that phytic acid, the storage form of phosphorus in seeds, nuts, beans, legumes, and grains, can bind to Mg in the gastrointestinal tract, making it less available to our bodies.

Regarding the Mg content in the diet, it is widely found in green leafy vegetables (Mg is in the center of the chloride ring of chlorophyll molecules), beans, legumes, and nuts, while processed foods are poor in this cation (see Table 22.2). In CKD and especially ESRD patients, the current dietary prescriptions that limit the intake of potassium may also lead to a low Mg intake. In contrast a vegetarian diet meets the daily nutrient requirement for Hemodialysis patients according to National Kidney Foundation guidelines [37].

Growing evidence supports the health benefits of plant-based diets, such as the *Dietary Approaches to Stop Hypertension* diet, which are high in Mg, fiber and low in saturated fat and have low levels of sodium for preventing heart disease and hypertension [54]. Contrary to traditional dietary recommendations that limit the intake of fruits and vegetables because of their high potassium content in patients with CKD, these patients should be encouraged to consume more plant-based proteins since it is well known that meat-based diets are typically much more acidic than plant-based diets, and there are health benefits associated with changing the acid–base balance in the diet.

Another concern among nephrologists is related to the possible risk of malnutrition associated with a vegetable-based diet since they are considered nutritionally inadequate, being deficient in all the essential amino acids and, therefore, dangerous for the management of patients with CKD. However, these vegetable-based diets are sufficient for a balanced protein intake [55]. In fact, the European Prospective Investigation into Cancer and Nutrition-Oxford support the idea that well-balanced and diverse vegetable-based diets can be nutritionally adequate and beneficial [56].

### Conclusion

Nephrologists should increase their awareness regarding the role of Mg in their patients since higher Mg serum levels might be associated with more favorable outcomes. Possible mechanisms underlying this association include protective effects of higher magnesium concentrations on the development of arrhythmia, ventricular hypertrophy, media VC, hypertension, and endothelial dysfunction. A low intake of fruits and

TABLE 22.2 Diet sources of Mg.

	Content of Mg	Potential benefits/particularities
<i>Whole grain</i> (wheat, oats and barley, as well as pseudocereals like buckwheat and quinoa)	A 1-ounce (28-g) serving of dry buckwheat contains 65 mg of Mg	<ul style="list-style-type: none"> <li>Many whole grains are also high in B vitamins, selenium, manganese, and fiber.</li> <li>They reduce inflammation and decrease CV risk</li> <li>Pseudo cereals like buckwheat and quinoa are higher in protein and antioxidants than traditional grains like corn and wheat; they also are gluten free so may be advise to patients with celiac disease [38,39]</li> </ul>
<i>Seeds</i> (including flax, pumpkin, and chia seeds)	Pumpkin seeds—150 mg of Mg in a 1-ounce (28-g) serving	<ul style="list-style-type: none"> <li>Seeds are rich in iron, monounsaturated fat, omega-3 fatty acids, and extremely high in fiber</li> <li>Antioxidant effect [40]</li> </ul>
<i>Dark chocolate</i> (at least 70% cocoa)	64 mg of Mg in a 1-ounce (24 g) serving	<ul style="list-style-type: none"> <li>It is also high in iron, copper, and contains prebiotic fiber [41]</li> <li>It contains flavanols that are powerful antioxidant [42]</li> </ul>
<i>Avocados</i>	One medium avocado provides 58 mg of Mg	<ul style="list-style-type: none"> <li>It is also high in potassium, B vitamins, and vitamin K and unlike most fruits monounsaturated fat</li> <li>They are an excellent source of fiber</li> <li>Eating avocados can reduce inflammation, improve cholesterol levels, and increase feelings of fullness after meals [43–45]</li> </ul>
<i>Nuts</i> (almonds, cashews, and nuts)	1-ounce (28-g) serving of cashews contains 82 mg of Mg	<ul style="list-style-type: none"> <li>A good source of fiber and monounsaturated fat and have been shown to improve glycemic control and dyslipidemia [46]</li> <li>Nuts also have antiinflammatory effects and reduce appetite when eaten as snacks [46,47]</li> </ul>
<i>Legumes</i> (lentils, beans, chickpeas, peas, and soybeans)	1-cup serving of cooked black beans contains an impressive 120 mg of Mg	<ul style="list-style-type: none"> <li>Legumes are also high in potassium and iron and a major source of protein for vegetarians [48]</li> <li>They are rich in fiber and have a low glycemic index [49,50]</li> </ul>
<i>Tofu</i>	3.5-ounce (100-g) serving has 53 mg of Mg	<ul style="list-style-type: none"> <li>Has high-protein content—one serving provides 10 g of protein and 10% or more of the RDI for calcium, iron, manganese, and selenium</li> <li>Potentially protects against gastric cancer [51]</li> </ul>
<i>Fatty fishes</i>	Half a fillet (178 g) of salmon packs 53 mg of Mg	<ul style="list-style-type: none"> <li>The fish meat is rich in potassium, selenium, and B vitamins</li> <li>A high intake of fatty fish has been linked to a decreased CV risk [52]</li> </ul>
<i>Leafy greens</i> (kale, spinach, collard greens, turnip greens, and mustard greens)	a 1-cup serving of cooked spinach has 157 mg of Mg	<ul style="list-style-type: none"> <li>They are a source of several nutrients, including iron, manganese, and vitamins A, C, and K.</li> <li>Reduce cancer risk [53]</li> </ul>

CV, Cardiovascular; RDI, recommended daily intake.

vegetables, the used of processed foods, low dialysate magnesium concentrations, or concurrent use of PPIs may put patients with CKD at risk for absolute or relative magnesium deficiency with detrimental effect for their outcome. Although Mg supplementation might represent an attractive option to these patients, this has to be confirmed in the future by higher evidence data.

# Calcium, phosphate, PTH, vitamin D, and FGF-23 in CKD-mineral and bone disorder

*Ezequiel Bellorin-Font, Alexandra Voinescu and Kevin J. Martin*

Division of Nephrology, Saint Louis University, St. Louis, MO, United States

In healthy individuals, kidneys play an important role in regulating calcium and phosphorus homeostasis through different mechanisms. Chronic kidney disease (CKD) is associated with the inability to control normal mineral homeostasis, resulting in changes in serum levels of calcium, phosphorus, parathyroid hormone (PTH), vitamin D, and fibroblastic growth factor (FGF-23). Secondary hyperparathyroidism (SHPT) is present in early stages of CKD, leading to the development of high bone turnover, pathological fractures, vascular calcifications, and other systemic manifestations. The term “CKD-mineral and bone disorder (CKD-MBD)” was introduced to define the biochemical abnormalities of calcium, phosphorus, PTH, vitamin D metabolism, abnormalities in bone turnover, volume and bone mineralization, and vascular or other soft-tissue calcifications [1,2]. This chapter will review the calcium, phosphorus, PTH, vitamin D, and FGF-23 axis, with the main focus on phosphorus and its central role in the pathophysiology and progression of CKD-MBD.

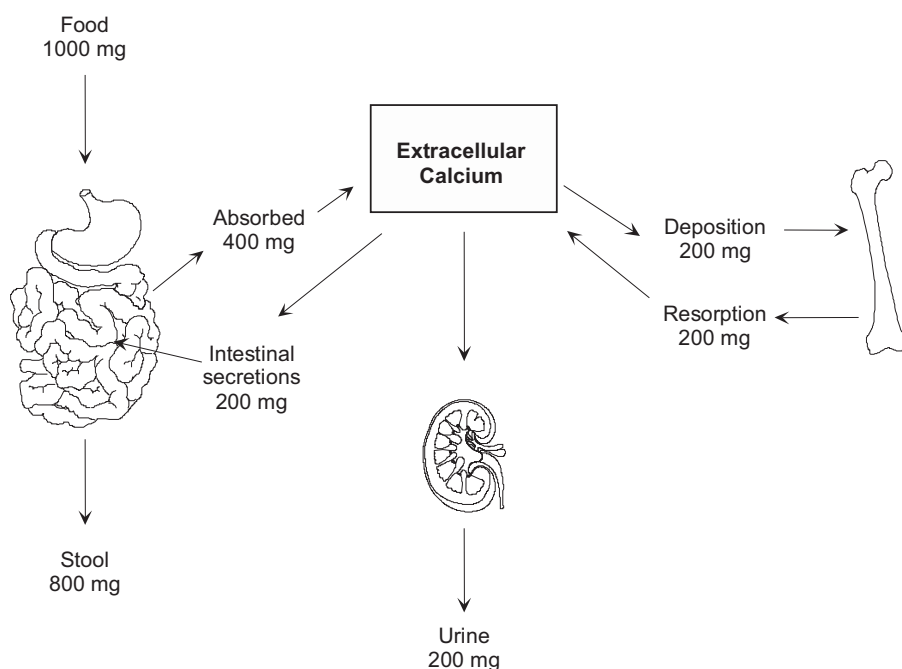

## Calcium metabolism

Calcium plays an important role in bone mineralization as well as a wide range of biological processes. Total body calcium content in adults is approximately 1000 g. Precisely 99% of total body calcium is in skeleton in the form of hydroxyapatite. The remainder is contained in the extracellular fluid and soft tissues. Serum and extracellular calcium concentration in humans is tightly controlled within a narrow physiologic range that is optimal for proper cellular functions of many tissues. Approximately 50% of the total serum calcium is ionized, and the remainder is bound primarily to

albumin (about 40%) or complexed with anions such as phosphate and citrate (about 10%). Serum calcium levels range between 8.5 and 10.5 mg/dL (2.1–2.6 mM) in healthy individuals. The ionized fraction of calcium is physiologically important and is regulated by the calcium-regulating hormones, PTH, and 1,25-dihydroxyvitamin D.

The average calcium dietary intake is around 1000 mg/day, but there are wide variations. On average, 400 mg of calcium undergoes net absorption from the diet, and the unabsorbed and secreted components appear in the stool. Yet from the extracellular pool of calcium, which contains about 900 mg, 10,000 mg/day is filtered at the glomerulus, most being reabsorbed by the renal tubules, and only a few hundred milligrams appearing in urine each day. This extracellular pool is in dynamic equilibrium with calcium entering and exiting via the intestine, bone, and renal tubules. The skeleton turns over about 200 mg/day of calcium, but there is wide variation (Fig. 23.1).

Intestinal calcium absorption occurs through two pathways: an active, transcellular, vitamin D-dependent pathway; and a passive, paracellular diffusional process. The duodenum is the major site of calcium absorption, although absorption occurs throughout the other segments of the small intestine and the colon. The active calcium uptake from the lumen across the brush border membrane occurs through TRPV5 (Transient Receptor Potential Cation Channel Subfamily V Member 5) and TRPV6 (Transient Receptor Potential Cation Channel Subfamily V Member 6) transporters located on the apical membrane. The transport of calcium through the cytosol requires a vitamin D-inducible protein, calbindin  $D_{9K}$ . At the basolateral membrane, calcium is removed from the cell by the  $Ca^{2+}$ -ATPase (PMCA1b) and an  $Na^{+}/Ca^{2+}$  exchanger (NCX1) [3]. Each of these steps is regulated by 1,25 (OH) $_2$  D.

**FIGURE 23.1** Diagram of calcium homeostasis showing dietary intake, the absorption and secretion of calcium by the intestine, skeletal deposition, and resorption and excretion of calcium by the kidney.

In the kidney, 60% of the filtered calcium is reabsorbed in the proximal tubule, mainly passively, through paracellular pathways via convection (solvent drag) and electrochemical gradients. Approximately 20% of calcium is reabsorbed in the thick ascending limb of the loop of Henle of which about two-thirds are paracellular and the remaining is transcellular. In addition, about 15% of the filtered calcium is reabsorbed in the distal convoluted tubule, the connecting tubule, and the initial part of the cortical collecting tubule. In this distal part of the nephron, calcium reabsorption actively opposes the natural electrochemical gradients. Luminal calcium enters the cells via the epithelial calcium channels, TRPV5 and TRPV6. Inside the cells, calcium binds with calbindin  $D_{28K}$  and is transported through the basolateral membrane via  $Ca^{2+}$ -ATPase (PMCA1b) and  $Ca^{2+}$ - $Na^{+}$  exchangers (NCX1). This active transcellular transport is regulated by PTH,  $1,25(OH)_2 D_3$ , calcium intake, and estrogens. PTH stimulates renal calcium reabsorption by upregulating the expression of the TRPV5, calbindin  $D_{28K}$ , NCX1, and PMCA1b [4]. Vitamin D receptor (VDR) null mice and 1- $\alpha$  hydroxylase-deficient animals show downregulation of TRPV5 and calbindin  $D_{28K}$ , demonstrating an important role of vitamin D in regulating renal calcium absorption [5]. Similarly, studies performed in VDR and 1- $\alpha$  hydroxylase knockout mice fed a high-calcium rescue diet showed upregulation of all four proteins [6]. It has also been demonstrated that estrogen upregulates the expression of TRPV5 in kidney in a  $1,25(OH)_2 D_3$ -independent manner [7].

## Vitamin D

Vitamin D is a multifunctional hormone that affects many essential biological functions, ranging from immune regulation to mineral ion metabolism. Vitamin  $D_2$  (ergocalciferol) is absorbed mainly from food, and vitamin  $D_3$  (cholecalciferol) is produced in the skin from 7-dehydrocholesterol by ultraviolet radiation (e.g., from sunlight). Both the forms of vitamin D require further metabolism to become activated, and their respective metabolism is indistinguishable. Vitamin D is transported in the blood by the vitamin D-binding protein (DBP) to the liver, where it is hydroxylated to  $25(OH)D$  (calcidiol), the major circulating metabolite of vitamin D. This hydroxylation is catalyzed by 25-hydroxylases, which are members of the cytochrome P450 expressed in the liver, predominantly by CYP27A1 and CYP2R1, but other hydroxylases that are components of the P450 family have also been identified [8]. The conversion of  $25(OH)D$  to the most active form of the hormone,  $1,25(OH)_2 D_3$  (calcitriol), occurs primarily in the kidney, but also in other extrarenal sites, by the action of the CYP27B1 ( $25(OH)D_3$  1- $\alpha$ -hydroxylase) [9].  $25(OH)D_3$  is transported to the kidney by DBP and filtered by the glomerulus. Uptake of  $25(OH)D_3$  occurs by endocytic internalization in the tubular epithelial cell by a megalin-dependent mechanism [10].  $25(OH)D$  is hydroxylated in the proximal tubule at the 1 position by the enzyme  $25(OH)D_3$ - $\alpha$ -hydroxylase (CYP27B1) to form  $1,25(OH)_2 D_3$  (calcitriol), the active form of vitamin D. Calcitriol production may occur in many tissues and

contributes to its circulating levels. Calcitriol circulates in plasma bound to DBP. Extrarenal production of CYP27B1 has been demonstrated in sarcoidosis and other conditions, resulting in hypercalcemia due to increased calcium absorption in the intestine. The source of CYP27B1 under these conditions is the macrophage [11]. Conversely, deletion or inactivation of CYP27B1 results in vitamin-dependent rickets type 1 regardless of normal intake of vitamin D.

PTH increases  $1,25(\text{OH})_2\text{D}_3$  by inducing CYP27B1. Synthesis of  $1,25(\text{OH})_2\text{D}_3$  can also be enhanced by low ambient calcium concentrations and phosphorus. Conversely  $1,25(\text{OH})_2\text{D}_3$  decreases its own synthesis by inhibiting CYP27B1. In addition, FGF-23 together with its coreceptor Klotho inhibits  $1,25(\text{OH})_2\text{D}_3$  production and increases the expression of CYP24A1, which promotes the catabolism of both  $1,25(\text{OH})_2\text{D}_3$  and  $25(\text{OH})\text{D}$  and leads to the production of  $24,25(\text{OH})_2\text{D}_3$ , a relatively inactive metabolite when compared to  $1,25(\text{OH})_2\text{D}_3$  [11]. In addition, a decrease in  $25(\text{OH})\text{D}$  results in reduction in the pool available for 1- $\alpha$  hydroxylation [12].

$1,25(\text{OH})_2\text{D}_3$  mediates its biological effects through its own member of the nuclear hormone receptor superfamily, the VDR, that acts as a ligand-inducible transcription factor. Ligand-bound VDR functions as a heterodimeric complex with the 9-*cis* retinoic acid nuclear receptor retinoid-X-receptor. The complex binds to target DNA sequences and regulates the transcription of several genes important in mediating the effects of vitamin D on calcium and skeletal metabolism and its diverse biological activities [13,14].  $1,25(\text{OH})_2\text{D}_3$  enhances the uptake of calcium in the intestine by increasing the expression of TRPV6 and the intestinal expression of calbindin. In the kidney,  $1,25(\text{OH})_2\text{D}_3$  enhances the expression of calbindin (9 kD in intestine and 28 kD in kidney), and the expression of the Ca ATP-ase at the basolateral membrane. It also stimulates intestinal phosphorus absorption.

Other effects of  $1,25(\text{OH})_2\text{D}_3$  include increase in bone formation and resorption. At the level of parathyroid gland,  $1,25(\text{OH})_2\text{D}_3$  reduces PTH synthesis and secretion, decreases PTH cell proliferation, and increases the expression of the Ca receptor, thereby sensitizing the parathyroid gland to inhibition by Ca [15,16].

In CKD,  $1,25(\text{OH})_2\text{D}_3$  production is compromised by a decrease in its synthetic apparatus in the diseased renal parenchyma, by a reduction in  $25(\text{OH})\text{D}_3$  levels and by the decrease in Glomerular Filtration Rate (GFR) that further limits the delivery of  $25(\text{OH})\text{D}_3$  to the site of the 1- $\alpha$ -hydroxylase in the proximal tubule [17]. Phosphate retention directly, or indirectly by inducing an increase in FGF-23, also decreases the activity of 1- $\alpha$ -hydroxylase and, therefore,  $1,25(\text{OH})_2\text{D}_3$  levels. Low levels of  $1,25(\text{OH})_2\text{D}_3$  directly

release the gene for PTH in the parathyroid cell from suppression by the VDR allowing an increase in PTH secretion [18]. This is aggravated by a decrease in VDR in the parathyroid cells of hyperplastic glands, which further limits the control of  $1,25(\text{OH})_2\text{D}_3$  on PTH secretion, favoring the development and progression of SHPT. The expression of VDR is even lower in nodular hyperplasia.

## Phosphate metabolism

Phosphate is an essential mineral critical for many biological processes, including bone development, cell membrane phospholipid content and function, cell signaling, and energy transfer mechanism. Abnormal phosphate metabolism is a key player in the development of the multiple mineral and bone disturbances that occur in CKD. Thus although overt hyperphosphatemia is observed late during the progression of CKD, a series of adaptive processes, including an increase in plasma FGF-23 and PTH concentrations, occur in early stages of the disease to increase phosphate excretion and maintain serum phosphate levels within a normal range. Therefore understanding phosphate balance is crucial for the interpretation of the effects that derangements in its metabolism have in mineral homeostasis, bone, and vascular tissue.

The total adult phosphorus content in the body is approximately 700 g. Precisely 80% is found in bone where it is linked with calcium to form hydroxyapatite crystals. The remainder of phosphorus is largely distributed in soft tissues, 14% intracellular, and only 10% in the extracellular space [19,20]. Plasma contains both organic and inorganic forms of phosphorus. The organic phosphorus fraction, found mainly in phospholipids, accounts for approximately two-thirds of the total plasma phosphorus. Inorganic phosphorus primarily exists as phosphate ( $\text{PO}_4$ ) and is the commonly measured fraction, present in concentration between 2.5 and 4.5 mg/dL. Precisely 15% of the inorganic phosphorus is bound to plasma proteins. The rest is complexed with sodium, magnesium, and calcium or circulates as the free monohydrogen ( $\text{HPO}_4^{2-}$ ) or dihydrogen forms ( $\text{H}_2\text{PO}_4^-$ ). Phosphorus has a pKa of 6.8, and at a normal physiologic body pH of 7.4, it primarily exists as a divalent ion in a ratio of about 4:1  $\text{HPO}_4^{2-}$  to  $\text{H}_2\text{PO}_4^-$ . The term "plasma phosphorus" is used when referring to plasma inorganic phosphorus concentration, and because plasma inorganic phosphorus is nearly all in the form of the  $\text{PO}_4$  ion, the terms "phosphate" and "phosphorus" are often interchangeably used in clinical chemistry laboratory [21].

The concentration of phosphorus in the extracellular space is the result of the interactions among intestinal

**FIGURE 23.2** Diagram of phosphorus homeostasis showing dietary intake, the absorption and secretion of phosphorus by the intestine, skeletal deposition, and resorption and excretion of phosphorus by the kidney.

uptake, renal tubular reabsorption, and exchange with bone and the intracellular compartment [20] (Fig. 23.2).

Phosphate intake by adults in developed countries ranges from 1000 to 1500 mg/day. Approximately 60%–80% of dietary phosphorus is absorbed along the entire length of the intestine but is maximal in the small intestine [22,23]. Intestinal phosphate absorption is linear and nonsaturable as a function of phosphate intake. Absorption occurs via two routes: a paracellular pathway involving tight junctions and driven by a passive diffusional flux, and an active transcellular transport involving the type II sodium-dependent phosphate cotransporter Npt2b. The energy for this transport process is provided by the sodium gradient induced by the sodium–potassium ATPase at the basolateral membrane [24]. Two additional type III sodium-dependent phosphate cotransporters, PiT1 and PiT2, have been found to be expressed in the intestine. The precise role of Pit transporters remains to be determined. In *NaPi-IIb*<sup>−/−</sup> mice, there is no residual sodium-dependent phosphate transport activity, suggesting that Pit-mediated transporters are of limited significance in the intestine [25,26]. The two major factors known to regulate Npt2b expression are dietary phosphate and 1,25(OH)<sub>2</sub>D<sub>3</sub>, which increases phosphate transport. Studies in both the VDR knockout mouse and the 1- $\alpha$ -hydroxylase knockout mouse have shown that Npt2b regulation by modulating dietary phosphate occurs through a vitamin D–independent pathway [25–28]. Other factors have been shown to modulate Npt2b expression, such as

estrogens, glucocorticoids, epidermal growth factor, metabolic acidosis, matrix extracellular phosphoglycoprotein (MEPE), and FGF-23 [29–34].

The kidneys play a major role in maintaining phosphorus balance by excreting the net amount of the absorbed phosphorus. As phosphorus is not significantly bound to albumin, most of the phosphorus is filtered freely at the glomerulus. At steady state, 80%–90% of the filtered phosphorus is reabsorbed by the kidneys. The proximal tubule reabsorbs 70%–80% of filtered phosphorus through type II sodium–phosphate cotransporters Npt2a and Npt2c, expressed at the apical membrane of renal proximal tubule cells. The type III phosphate transporter PiT-2 has been shown to contribute to phosphate absorption in the proximal tubules. Knockout studies in mice have shown that 70% of the renal phosphate absorption is mediated by Npt2a and approximately 30% by Npt2c. Double-knockout *Npt2a/Npt2c* mice still exhibit some renal phosphate reabsorption, indicating a role for PiT-2 in this process [35–38]. Phosphate transport across the basolateral membrane remains a poorly understood process. Several phosphate transport pathways have been postulated, including a phosphate-anion exchanger, passive diffusion, or phosphate transport via type II sodium–phosphate cotransporters.

Several factors that stimulate renal phosphate transport include phosphate depletion, insulin-like growth factor-1, growth hormone, thyroid hormone, 1,25(OH)<sub>2</sub> vitamin D<sub>2</sub> phosphate [38–41]. Factors that inhibit phosphate reabsorption include PTH, FGF-23,

phosphate loading, volume expansion, metabolic acidosis, glucocorticoids, and calcitonin [42–44]. The main hormones that regulate renal phosphate handling are PTH and FGF-23. In CKD the fractional excretion of phosphate may exceed 50% to compensate for the loss of functioning nephrons.

### Parathyroid hormone

PTH is an 84-amino acid protein synthesized in the parathyroid gland and stored in secretory granules which release PTH in response to a reduction in the levels of ionized calcium, hyperphosphatemia, and/or  $1,25(\text{OH})_2\text{D}_3$  deficiency. Following release, PTH 1–84 has a relatively short half-life in plasma of just minutes and is cleaved into a variety of fragments of the hormone in the liver and kidney. Several mechanisms are involved in the regulation of PTH synthesis and secretion by the parathyroid gland. Calcium sensing receptor (CaSR), the VDR, phosphate, and FGF-23 are determinants for parathyroid gland function. Calcium, the main regulator of PTH secretion, acts by the activation of the CaSR, a G protein–coupled receptor that modulates PTH secretion directly [45]. CaSR is activated by elevations in extracellular Ca concentration, leading to the inhibition of PTH, whereas low serum-ionized calcium increases PTH secretion. Vitamin D, acting through the VDR, regulates PTH by the inhibition of PTH mRNA expression. In addition,  $1,25(\text{OH})_2\text{D}_3$  has an indirect suppressive effect on PTH, by increasing intestinal Ca absorption.

In CKD, low serum calcium, resulting from decreased intestinal calcium absorption due to low  $1,25(\text{OH})_2\text{D}_3$  levels, leads to an increase in PTH secretion. Studies in experimental animals indicate that signal transduction via the CaSR is a determinant of parathyroid cell proliferation and can lead to parathyroid gland hyperplasia [45]. Studies show that parathyroid cells from parathyroid hyperplastic tissue are less sensitive to the inhibitory effect of calcium [46]. Other studies in normal rats and rats with CKD indicate that parathyroid cell hyperplasia is associated with a decrease in CaSR and VDR expression. Furthermore, resected parathyroid glands from patients with severe SHPT have nodular areas throughout the gland that represent monoclonal expansion of parathyroid cells. These cells have reduced the expression of CaSR and VDR, which decreases their sensitivity to the inhibitory effects of calcium and  $1,25(\text{OH})_2\text{D}_3$  on PTH secretion and consequently favors more severe SHPT [47]. A direct consequence of these alterations is an increased difficulty in controlling PTH levels in patients with SHPT and enlarged parathyroid glands.

The precise mechanism of the regulation of PTH secretion by phosphate is not completely understood. Hyperphosphatemia may affect the regulation of intracellular Ca in parathyroid cells, resulting in the inhibition of phospholipase A2 (PLA2) and diminished synthesis of arachidonic acid (AA) formation, the latter being a potent inhibitor of PTH release [48]. Hyperphosphatemia is also associated with reduced expression of the CaSR, thereby decreasing the ability of the parathyroid gland to respond to changes in ionized Ca [49]. In addition, high phosphate intake induces parathyroid cell proliferation and growth through transforming growth factor alpha (TGF- $\alpha$ ), mediated via the epidermal growth factor receptor, resulting in parathyroid hyperplasia and the development of SHPT [50,51].

In the kidney, PTH binds to type I PTH receptor in proximal tubular cells [52] and thereby activates cyclin adenosine monophosphate (cAMP)-protein kinase A and the phospholipase C-protein kinase C signal transduction pathways. Activation of both signaling pathways leads to the internalization of the sodium–phosphate cotransporters Npt2a and Npt2c, leading to increased phosphate excretion. The removal of Npt2a from the apical brush border membrane in response to PTH requires the presence of the sodium–proton exchanger regulatory factor 1. After the removal of the exchanger from the brush border in response to PTH, Npt2a is sent to early endosomes and then to lysosomes, where subsequent proteolytic degradation of the transporter occurs [43,53,54].

### Measurement of PTH levels

Measurement of plasma PTH is essential for the assessment of abnormalities in PTH secretion, and particularly the assessment of disturbances in bone and mineral metabolism in the setting of CKD. Measurement of PTH has been complicated by the existence of circulating PTH fragments and their recognition by particular hormone assays, and a lack of standardization of the assays. PTH assays have evolved from first generation, in which a polyclonal antibody was used for the recognition of circulating PTH, to a second generation using two specific antibodies to the carboxy-terminus and amino-terminus portion of the hormone, respectively, with the ability to capture the 1–84 molecule. However, these assays also recognize 7–84, a fragment that frequently circulates in patients with CKD, resulting in overestimation of the PTH level [55]. Third-generation assays use more specific antibodies against the N-terminal portion of the molecule and, thus, are able to capture the whole PTH molecule [56,57]. Comparisons between second- and third-generation assays have given good results [58], but the difference between results become

significant as PTH levels increase. The interpretation of the PTH assay is important from the clinical standpoint because current guidelines deal with plasma PTH levels. The guidelines make recommendations for treatment based on trend monitoring, the use of a fold-increase of the upper reference limit [1,2], or cutoffs for initiating or stopping treatment in patients with CKD. Therefore it is important to take into account what PTH assay is used to monitor the patient and to make clinical decisions [59].

### **Fibroblast growth factor-23 and Klotho**

The term “phosphatonin” was originally described as a circulating factor that caused renal phosphate wasting in patients with tumor-induced osteomalacia (TIO), a paraneoplastic syndrome characterized by renal phosphate wasting, aberrant vitamin D metabolism, and osteomalacia. Search for phosphatonin in patients with TIO led to the identification of FGF-23. In addition to FGF-23, other identified phosphatonins include secreted frizzled-related protein 4, MEPE, and FGF-7 [60–67]. FGF-23 is the bone-derived phosphatonin that has been extensively studied and has been found to play a critical role in normal physiology and altered mineral metabolism in CKD.

FGF-23 is a 32-kDa, 251 amino acid protein, predominantly expressed in osteocytes and osteoblasts in the skeleton, but low levels of unclear significance can be found in pericyte-like cells that surround the venous sinusoids of the bone marrow, ventrolateral thalamic nuclei, heart, thymus, and small intestine [68,69].

The kidney is the main target organ for FGF-23. Injection of recombinant FGF-23 into animals induces a rapid decline in renal phosphate reabsorption, resulting in hypophosphatemia, low serum calcitriol levels, and bone demineralization. FGF-23 activates FGF receptors on the basolateral membrane of the renal tubules resulting in decreased expression of Npt2a and Npt2c on the apical surface of the tubular cell. The reduction in the number of Npt2a by FGF-23 seems to be independent of PTH [70]. FGF-23 also suppresses the  $1\alpha$ -hydroxylase enzyme (CYP27B1) in the renal tubule, the enzyme that stimulates the conversion of 25-hydroxyvitamin D to  $1,25(\text{OH})_2\text{D}$ . FGF-23 also enhances the expression of 24-hydroxylase (CYP24), which converts  $1,25(\text{OH})_2\text{D}$  to inactive metabolites in the proximal renal tubules [26,71,72]. FGF-23 exerts its biological functions by binding to the Fibroblast Growth Factor Receptor, (FGFR), which requires full-length Klotho as coreceptor, a type I membrane receptor with homology to beta-glycosidases [73,74]. The transmembrane and secreted forms of Klotho proteins may collectively affect the aging process in mammals [75].

Klotho expression is restricted to a few tissues, including the distal convoluted tubules in the kidney, parathyroid glands, the sinoatrial node, the pituitary gland, and the choroid plexus in the brain. It is still unclear how FGF-23 exerts its physiological effects on the proximal tubule in the kidney since Klotho appears to be expressed in the distal tubular epithelial cells. It has been shown that Klotho is expressed at the cell surface, but its extracellular domain could be shed by secretases and released into the circulation to act as an endocrine factor. In the kidney, FGF-23 binds to the complex FGFR-Klotho to activate extracellular signal-regulated kinases and serum/glucocorticoid-regulated kinase, which ultimately leads to the downregulation of membrane expression of the sodium transporter NaPi-2A, resulting in an increase in urinary phosphate excretion [76,77]. Klotho also may undergo cleavage at the cell surface and release to the circulation and may directly regulate calcium and phosphorus excretion in the kidney,  $1\alpha$ -hydroxylase activity, PTH, and FGF-23 [78,79]. In Klotho-deficient mice the FGF-23 concentration is increased but is ineffective in controlling serum phosphate levels. In conclusion, Klotho is a coreceptor that specifically increases the sensitivity of FGF receptors to FGF-23 [54,73,74,80].

Under conditions of Klotho deficiency in the renal tubule, there is a decrease in the phosphaturic effect of FGF-23 [81]. Low Klotho expression has been observed in kidneys of patients with CKD stage 1, and Klotho expression decreases progressively as CKD advances. This decrease in Klotho is followed by reduction in  $1,25(\text{OH})_2\text{D}_3$ , and increase in serum FGF-23 and intact PTH, which becomes significant in stage 3 CKD [79]. A result of the decrease of Klotho as renal function declines is a loss of the negative feedback for FGF-23 secretion by the osteocyte and an increase in FGF-23 levels, which allows FGFR activation independent of Klotho. This leads to an increase in the fractional excretion of phosphate, which would, in turn, lead to the normalization of serum Pi levels despite falling renal Klotho expression. In advanced CKD, by contrast, levels of Klotho are not sufficient to support renal FGF-23-Klotho signaling; thus FGF-23 cannot compensate for the renal failure-induced P retention. Consequently, elevated serum phosphate becomes the main regulator of FGF-23 in advanced CKD [78]. In conclusion, Klotho is a coreceptor that specifically increases the sensitivity of FGF receptors to FGF-23 [54,73,74,80] and seems to play a role in the pathogenesis of the early changes in renal phosphate handling in CKD.

Since renal Klotho starts to decline in mild CKD and precedes elevations of FGF-23, it has been suggested that Klotho levels can be utilized as surrogate markers for renal Klotho and as a sensitive early marker of loss of renal function. However, preclinical animal data indicate that Klotho deficiency is not just

merely a biomarker, but a pathogenic factor for CKD progression and extrarenal CKD complications, including cardiovascular disease (CVD) and disturbed mineral metabolism.

Besides its effect on tubular phosphate handling, FGF-23 may affect PTH synthesis and secretion. Injection of FGF-23 in animals rapidly decreases PTH secretion, within 10 minutes, through the Mitogen Activated Kinase (MAPK) pathway; FGF-23 also inhibits PTH gene expression in parathyroid glands. In addition, FGF-23 increases 1-alpha-hydroxylase expression in bovine parathyroid cells, which may contribute to the reduced PTH gene transcription [54,82,83].

FGF-23 gene expression in bone is regulated by phosphate and  $1,25(\text{OH})_2\text{D}_3$ . Phosphate loading in mice increases FGF-23 levels, but the data in humans are conflicting. Some studies fail to demonstrate an increase in serum FGF-23 levels in response to phosphate loading, whereas phosphate restriction has been associated with a small, but significant, decrease in circulating FGF-23 levels. Extracellular phosphorus did not directly stimulate FGF-23 mRNA levels or FGF-23 gene promoter activity in osteoblastic cultures [84–88].  $1,25(\text{OH})_2\text{D}_3$  stimulates FGF-23 production both in vivo and in vitro. This effect seems to be mediated through the VDR since VDR-null mice did not show an increase in FGF-23 levels in response to  $1,25(\text{OH})_2\text{D}_3$  administration. FGF-23 secretion is also regulated by local bone-derived factors, such as phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX) and dentin matrix protein 1 [68,89].  $1,25(\text{OH})_2\text{D}_3$  is also able to suppress PHEX mRNA levels in bone cells, and reductions in PHEX can increase FGF-23 expression in osteocytes. Therefore it is plausible that  $1,25(\text{OH})_2\text{D}_3$  upregulates FGF-23 production in part indirectly by the downregulation of PHEX expression [90–94].

### Alterations in mineral metabolism in CKD

Phosphate retention begins at an early stage of CKD, due to a gradual decline in filtered phosphate load. However, serum phosphate is maintained within normal limits until the GFR falls to less than approximately 30 mL/min [22,95]. As renal function declines, serum phosphate levels are maintained by reducing phosphate reabsorption in the remaining nephrons by FGF-23. However, this effect is limited due to proximal tubule Klotho deficiency occurring early in the course of CKD [18,79,96]. As a consequence, serum PTH increases to further reduce tubular phosphate reabsorption and maintain phosphate balance. As renal insufficiency continues to progress, FGF-23 and PTH are no longer enough to maintain phosphate homeostasis, and hyperphosphatemia develops. Both

phosphate and FGF-23 inhibit 1-alpha-hydroxylase in the kidney leading to a decrease in  $1,25(\text{OH})_2\text{D}_3$  synthesis and the development of  $1,25(\text{OH})_2\text{D}_3$  deficiency. Phosphate increases serum PTH independent of serum calcium and  $1,25(\text{OH})_2\text{D}_3$  (calcitriol). In addition, calcitriol deficiency decreases intestinal calcium absorption leading to hypocalcemia, and diminished tissue levels of VDRs, which in the parathyroid gland results in resistance to calcitriol-mediated regulation and elevation of PTH secretion. All these factors lead to SHPT. As these alterations continue, nodular hyperplasia of parathyroid gland occurs, and the physiological mechanisms controlling PTH secretion become ineffective. The persistent actions of elevated PTH increase bone turnover, resorption and frailty, and consequently elevated fracture risk [18].

Because  $1,25(\text{OH})_2\text{D}_3$  is also a potent inducer of Klotho expression in the kidney, decreased levels of  $1,25(\text{OH})_2\text{D}_3$  reduce Klotho expression. FGF-23 suppresses PTH release via stimulating the dimeric Klotho-FGF receptor at the parathyroid glands, but resistance to the effect of FGF-23 appears as kidney function declines because of decreased Klotho expression in the parathyroid glands and kidney. Thus as renal function continues to decline, hyperphosphatemia develops progressively due to insufficient renal excretion despite high serum levels of PTH and FGF-23. Increased bone resorption in response to chronically elevated PTH levels can also contribute to the hyperphosphatemia observed in CKD and end-stage renal disease patients [97–101].

The effects of hyperphosphatemia are multifactorial. They include (1) a decrease in serum calcium levels through physicochemical binding; (2) suppression of 1-alpha-hydroxylase activity, resulting in decreased levels of  $1,25(\text{OH})_2\text{D}_3$ , which causes direct increase in PTH secretion; (3) a direct effect of phosphorus on parathyroid gland cells stimulating PTH secretion, independent of serum calcium and  $1,25(\text{OH})_2\text{D}_3$  [48,102,103]; (4) inhibition of PLA2 and the formation of AA, a potent inhibitor of PTH release [104]; and (5) a reduction in the expression of the CaSR (calcium-sensing receptor), thereby decreasing the ability of the parathyroid gland to respond to changes in ionized calcium [49]. In addition, high phosphate intake induces cell growth by increasing the expression and actions of TGF- $\alpha$  which are mediated through the epidermal growth factor receptor; this worsens parathyroid hyperplasia and the resultant SHPT [50]. The effect of phosphate on PTH gene expression involves changes in the cytosolic proteins in the parathyroid gland that bind to the PTH mRNA 3' untranslated region and determine PTH mRNA stability. Further studies have shown decreased PTH mRNA degradation in animals with uremia [105,106].

## Phosphate and cardiovascular disease

Although a causal relationship between serum phosphate levels and poor clinical outcomes has not been demonstrated, concern about this association has increased the interest in reducing serum phosphate levels as a means to control cardiovascular (CVS) mortality. KDIGO guidelines suggest lowering elevated serum phosphate levels toward the normal range in CKD 3–5D (2C), and that decisions about phosphate-lowering treatment should be based on progressively or persistently elevated serum phosphorus [2].

Numerous studies have shown, that in addition to its central role in SHPT, there is an association between high phosphate levels and CVS and all-cause mortality in patients with advanced CKD [13,14,19,21,22] and also in the general population. Indeed, epidemiologic data suggest that higher serum phosphate levels are associated with increased CVS morbidity and mortality in both the general and CKD populations. The Framingham Offspring Study evaluated 3368 participants with no history of CKD or CVD and found that serum phosphate levels greater than 3.5 mg/dL were associated with an estimated 55% increased CVD risk [107]. In a post hoc analysis of the Cholesterol and Recurrent Events study, participants with serum phosphate greater than 4 mg/dL had a 50% greater risk of myocardial infarction [hazard ratio (HR), 1.50; 95% confidence interval (CI), 1.05–2.16] and a 43% greater risk of developing heart failure (HR, 1.43; 95% CI, 0.95–2.14) compared with those with serum phosphate of 2.5–3.4 mg/dL. Each 1 mg/dL higher serum phosphorus level was associated with a 27% increased risk for all-cause mortality (HR, 1.27; 95% CI, 1.02–1.59) [108]. The relationship between phosphate excess and CVS risk has also been studied in CKD patients. In a study of 3490 veterans with CKD stage 3–4, each 1-unit increase in serum phosphate was associated with a significant 35% increased risk for acute myocardial infarction (HR, 1.35; 95% CI, 1.09–1.66) and a 23% greater risk of mortality (HR, 1.23; 95% CI, 1.12–1.36) after adjustments for comorbid conditions [109].

Another large prospective longitudinal study performed in nondialyzed CKD patients was the Chronic Renal Insufficiency Standards Implementation Study, which involved 1203 patients. In CKD stages 3–4 patients, all-cause and CVS mortality risk increased as serum phosphorus increased [110]. Phosphate was initially identified as a CVS risk factor in dialysis patients in 1998 in a cohort of 6407 hemodialysis patients, followed by another study done in 2004 in 40,538 patients from the US Renal Data System, where there was a linear association of higher serum phosphate concentrations with a greater risk of CVS hospitalizations [111,112]. In another study conducted in 14,829

hemodialysis patients, the fully adjusted risk of CVS events was greater with incrementally higher serum phosphate concentrations [113].

Multiple studies performed in dialysis patients confirm the association of higher serum phosphate levels with mortality, although there were slight differences in the inflection point (the point at which the serum phosphate level becomes significantly associated with increased all-cause mortality) that varied from 5.0 to 5.5 mg/dL [112], greater than 5.5 mg/dL [114], 6.0 to 7.0 mg/dL [115], and greater than 6.5 mg/dL [116].

The mechanisms underlying the increase in CVS morbidity and mortality associated with disturbances in phosphate metabolism are not fully understood but may involve direct effects of increased phosphate on renal bone disease and vascular calcification, as well as modulation of circulating serum hormones, such as FGF-23, PTH, and calcitriol. Serum phosphate levels are also associated with CKD progression and left ventricular hypertrophy, which may contribute to CVD and death [117–119]. High FGF-23 levels were found to be an independent predictor of mortality in both incident and prevalent dialysis patients [120–123]. These effects are independent of serum phosphate, and the correlation between high serum FGF-23 and mortality remains significant even in patients with normophosphatemia. Thus even in the general population, serum FGF-23 is associated with increased mortality [117]. It is unclear whether increased FGF-23 levels are directly toxic or are a surrogate marker of the toxicity of other factors that are implicated in the development of vascular disease. Several studies demonstrate that high FGF-23 levels are associated with impaired vasoreactivity and arterial stiffness, increased left ventricular mass index, and increased prevalence of left ventricular hypertrophy in CKD patients [120,124–126]. FGF-23 is also associated with congestive heart failure [127].

Experiments in animals have shown direct cardiac effects of FGF-23 on the hypertrophy, contractility, and arrhythmic potential of the myocardium [128,129], and indirect effects on the heart by activation of the renin–angiotensin system and promotion of sodium reabsorption in the distal tubule of the kidney. It has been hypothesized that elevation of FGF-23, while necessary to control phosphate and vitamin D homeostasis, may also contribute to the development of CVD [127].

Another possible mechanism by which phosphate may influence CVS risk is by stimulating PTH secretion and inhibiting the activation of vitamin D. PTH excess and 1,25(OH)<sub>2</sub>D deficiency are associated with increased CVS risk in some observational studies. Calcitriol potentially suppresses the renin–angiotensin–aldosterone system and regulates cardiomyocyte proliferation and hypertrophy [111,112,130,131]. FGF-23 inhibits 1- $\alpha$ -hydroxylase in the kidney, resulting in decreasing

1,25-dihydroxyvitamin D synthesis. Further studies are needed to identify if phosphate increases CVD through a mechanism that involves vitamin D. Regardless of the underlying mechanisms, it is important to consider phosphate levels as a key factor in the generation of CKD-mineral and bone disorder (CKD-MBD).

## Phosphate and vascular calcifications

Vascular calcification has been recognized as a common complication of CKD for many years. Calcium phosphate deposition is the hallmark of vascular calcifications and can occur in blood vessels, myocardium, and cardiac valves. There are two types of arterial calcifications. Intimal calcification occurs within atherosclerotic plaques. Arterial medial calcification or Monckeberg's sclerosis occurs at the internal elastic lamina of the media layer. This type of vascular calcification is more common in patients with CKD, diabetes mellitus, and advanced aging. Similar to intimal calcification, the presence of arterial medial calcification is a powerful and independent prognostic marker for all cause and CVS mortality in end-stage renal disease patients [132].

The presence of atherosclerotic vascular disease is often associated with the development of plaques and occlusive lesions. Medial wall calcification is known to be associated with increased arterial stiffness and reduced vascular compliance, and increased pulse wave velocity. These hemodynamic changes lead to left ventricular hypertrophy, compromised coronary blood flow during diastole, and increased CVS and all-cause mortality. Arterial medial calcification can also involve the small arterioles of the skin, causing calciphylaxis, a condition associated with extremely high mortality rates in dialysis patients [133,134].

Vascular calcification can be detected by a number of radiologic techniques. Plain radiography is the simplest technique used to detect the presence or absence of vascular calcification. Although some degree of differentiation between medial and intimal calcification can be detected on plain radiographs, this technique is insensitive and difficult to quantify [132]. Other techniques that have been used include vascular ultrasonography which can identify calcified plaques and calcified media, and intravascular ultrasonography, a more accurate technique that allows for the measurement of absolute cross-sectional luminal areas [135,136]. For coronary artery calcifications, other non-invasive techniques such as tomography-based approaches [electron beam CT (computerized tomography) (EBCT) and multislice CT] permit assessment and quantification of the extent of calcifications. Braun et al. reported that EBCT has a sensitivity of 93% and a

specificity of 73% when angiography was used as the reference standard. These CT-based techniques do not allow differentiating atherosclerotic calcifications and medial calcification [133,137].

Bellasi et al. compared different simple, noninvasive techniques to detect calcification with those obtained using electron beam tomography (EBT) for coronary artery calcium (CAC) scoring in 140 prevalent hemodialysis patients [138]. All patients underwent EBT imaging, a lateral X-ray of the lumbar abdominal aorta, an echocardiogram, and measurement of pulse pressure (PP). Calcification of the abdominal aorta was scored as 0–24 divided into tertiles, echocardiograms were graded as 0–2 for the absence or presence of calcification of the mitral and aortic valve, and PP was divided in quartiles. The likelihood ratio (95% CI) of coronary artery calcification score by an EBCT of greater or equal to 100 was 1.79 (1.09, 2.96) for the calcification of either valve and 7.50 (2.89, 19.5) for participants with a lateral abdominal radiographic-score greater or equal to 7. In contrast, no association was present between PP and EBCT calcification score [138]. KDIGO guidelines recommend the use of plain lateral abdominal radiography or echocardiography to detect the presence or absence of coronary artery calcification in end-stage renal disease patients [1].

The prevalence of vascular calcifications varies according to age, method of detection, site of measurement, time on dialysis, and diabetic status. Goodman et al. found that coronary artery calcification occurs more frequently in young dialysis patients (between 20 and 30 years of age) compared to either normal subjects of the same age and sex or older adults with normal renal function [139]. Another study showed that coronary artery calcification by EBCT increased with advancing age in patients on dialysis and that the calcification scores were two to fivefold higher in the dialysis patients than in age-matched nondialysis patients with angiographically proven coronary artery disease [137]. An autopsy study done in 54 cases was designed to compare morphology and immunohistology of coronary arteries and coronary plaques of patients with End Stage Renal Disease (ESRD) and matched nonrenal patients who had died from a cardiac event. The magnitude of atherosclerotic plaque burden and intimal thickness in the dialysis patients was similar to the nonuremic controls. Coronary plaques in patients with end-stage renal disease were characterized by increased media thickness and marked calcification [140]. The prevalence of detectable coronary and peripheral artery calcifications in dialysis patients ranges from 30% to 92%, according to age, sex, dialysis duration, and site of measurement [137,141,142]. The earliest and commonest site of calcification is the ankles, followed in frequency by the abdominal aorta,

feet, pelvis, and hands and wrists in radiographs. Valvular calcifications are also common in dialysis patients. EBCT studies showed a prevalence of 45%–59% in the mitral valve and 34%–55% in the aortic valve [137,143].

There are limited data concerning the prevalence of coronary artery calcification using CT in CKD patients not yet on dialysis. Kramer et al. evaluated the association between CKD and coronary artery calcification among 2660 patients in the Dallas Heart Study aged 30–65 years. No association was noted between stages 1 and 2 CKD and increased coronary artery calcification scores. Compared with no CKD, stages 3–5 CKD were associated with increased risk of having increased coronary artery calcification, particularly very high calcification scores. This was largely due to the inclusion of patients with diabetes as there was no significant association between increased coronary artery calcification scores and the nondiabetic population who had stages 3–5 CKD [144].

Several studies demonstrate that coronary artery calcification is associated with increased mortality in dialysis patients. In a prospective study conducted in 110 dialysis patients, the authors correlated the amount of baseline vascular calcification (as assessed by ultrasonography at four different anatomic sites) with survival during a period of more than 4 years of follow-up. The results of this study showed that the presence and extent of vascular calcifications were strong predictors of CVS and all-cause mortality [145].

One study followed 127 incident hemodialysis patients prospectively after baseline EBCT and demonstrated that the severity of coronary artery calcification at the time of initiation of hemodialysis is an important predictor of long-term survival. Even after adjustment for age, race, gender, and diabetes, a baseline CAC greater than 400 was associated with a greater than fourfold increase in mortality [146].

Hyperphosphatemia has been linked to arterial calcifications in several human observational studies and in cell culture models. In a small study of dialysis patients, the mean serum phosphorus concentration was higher among the patients with coronary artery calcification [139]. Adeney et al. evaluated 439 participants from the Multi-Ethnic Study of Atherosclerosis who had moderate CKD and no clinical CVD. After adjustment for demographics and estimated GFR, each 1 mg/dL increment in serum phosphate concentration was associated with a 21% ( $P = .002$ ), 33% ( $P = .001$ ), 25% ( $P = .16$ ), and 62% ( $P = .007$ ) greater prevalence of coronary artery, thoracic, aortic valve, and mitral valve calcification, respectively [147]. The relationship between serum phosphate levels and vascular calcification was also evaluated in the general population. In 3015 healthy young adults in the prospective Coronary

Artery Risk Development in Young Adults study, phosphorus levels were measured at baseline, and the presence of CAC was assessed by computed tomography 15 years later. Serum phosphate levels greater than 3.9 mg/dL had a 52% greater risk of coronary artery calcifications as compared with those with a phosphate level less than 3.3 mg/dL (adjusted OR, 1.52; 95% CI, 1.04–2.22) [148]. High serum phosphate level was also found to be associated with vascular stiffness in the general population. The association between serum phosphorus levels and arterial stiffness as estimated by an ankle brachial pressure index (ABPI) was examined in 581 participants with normal renal function in the third National Health and Nutrition Examination Survey. There was a strong association between the highest quartile of serum phosphorus (3.7–5.0 mg/dL) and high ABPI compared to the reference group (3.1–3.4 mg/dL) after multivariate adjustment (adjusted OR, 4.78%; 95% CI, 1.73–13.2;  $P = .003$ ) [149,150]. The findings from previous studies suggest that high serum phosphate levels are a risk factor for the development of vascular calcifications. Lowering serum phosphate levels with a noncalcium-based phosphate binder was found to slow the progression of vascular calcification in end-stage renal disease patients [151,152]. Several animal studies pointed to a role of elevated phosphorus in vascular calcification. Uremic rats treated for 3 months with a high-phosphate diet showed aortic medial calcification that was decreased by treatment with the noncalcium phosphate binder, sevelamer [153].

Vascular calcification is a highly regulated process and occurs as a result of (1) phenotypic transformation of vascular smooth muscle cells (VSMCs) into osteochondrogenic-like cells, (2) the stimulation of these cells to actively synthesize mineralization-initiating matrix vesicles, (3) VSMC apoptosis with the release of calcifying apoptotic vesicles, and (4) an imbalance of systemically and locally produced promoters and inhibitors of mineralization.

Several studies have described the ability of serum phosphorus to potentially stimulate the phenotypic transformation of VSMCs into osteoblasts capable of producing a promineralizing milieu. In a hyperphosphatemic environment ( $P_i > 2.4$  mM), the VSMC culture systems revealed both osteochondrogenic phenotypic change and mineralization through the sodium-dependent phosphate transporter, Pit-1. These in vitro and animal experiments demonstrate that phosphate plays a key role in controlling vascular calcification [154–156].

In addition to vascular calcification, heart valve calcification occurs with a higher prevalence and at lower age in CKD compared with non-CKD patients and carries an increased risk of death and other clinical consequences [143,157–159]. Indeed, in a recent

analysis of several publications comprising more than 600 patients, it was shown that in CKD patients the prevalence of calcification varied between 25% and 59% in the mitral valve, and 28% to 55% in the aortic valve [160]. There is an association between serum phosphate concentrations and aortic and mitral valve calcification [160,161]. In addition, the extent of aortic valve calcification has been associated with FGF-23, hyperparathyroidism, and sclerostin [162].

### Control of serum phosphate in CKD

In 2003 the National Kidney Foundation released the Kidney Disease Outcomes Quality Initiative (KDOQI) clinical practice guidelines for bone metabolism and disease in CKD. KDOQI recommended targeting serum phosphorus levels at 2.7–4.6 mg/dL in patients with CKD stages 3 and 4 and 3.5–5.5 mg/dL in those with CKD stage 5D. In contrast, KDIGO guidelines from 2017 reaffirmed the need to decrease serum phosphate levels in CKD 3–5D toward the normal range.

As discussed previously, during the early stages of CKD, a rise in serum FGF-23 and PTH maintains serum phosphate levels within the normal range. Therefore a relative reduction in phosphate intake seems logical as a mean to decrease the amount of phosphate absorbed in the intestine and consequently, to decrease FGF-23 and PTH secretion. Indeed, in early experimental studies done in uremic dogs, dietary phosphorus reduction in proportion to the reduction in GFR was effective in preventing the development of hyperparathyroidism during a period of 2 years of observation, suggesting a critical role for phosphate retention in the elevation of PTH [163]. However, in clinical terms, the use of phosphate-lowering agents at these stages of CKD is highly controversial as there is no hard evidence of better outcomes in terms of SHPT [2]. In addition, the determination of the amount of phosphate binders required is difficult, because serum phosphate levels at these stages will not express the state of phosphate balance. Alternative biomarkers, such as FGF-23 or urinary phosphate excretion, may become important measures of altered phosphorus metabolism not reflected in serum levels and may indicate the need for treatment in earlier stages of CKD, before the onset of hyperphosphatemia.

In CKD stages 3 and 5D, increases in serum FGF-23 and PTH are not sufficient to control phosphate levels. As discussed later, counseling on nutritional recommendations to reduce phosphate intake by diminishing protein consumption and adequate selection of the protein source (animal vs vegetable, food additives, medications, etc.) are central to the management of

phosphate burden [164,165]. However, patient's compliance frequently limits the effectiveness of protein-restricted diets in reducing phosphate burden and the control of hyperphosphatemia. Furthermore, controversy exists as to the extent of dietary protein restriction in patients with advanced renal disease in which nutritional status may be already compromised by the disease. Hence, most patients will require the use of phosphate binders to decrease intestinal absorption and dialysis therapy to remove phosphorus from the body. Despite these measures, less than 50% of dialysis patients meet target levels for serum phosphorus [166]. In another study conducted in 1814 CKD patients (SEEK study), only 15% of patients had a serum phosphate level less than 4.6 mg/dL when their GFR was 20–29 mL/min [95]. The multifactorial reasons for the suboptimal phosphate control include late referral to a nephrologist with subsequent late start of dietary phosphate restriction and fear that tight phosphate restriction may represent a risk for protein malnutrition. Once counseling for phosphate-lowering is initiated, other challenges appear, including poor adherence to dietary restrictions, the phosphate binder pill burden, and the cost of the phosphate binders. Hence, solid knowledge of phosphorus content of different foods is essential to the clinical management of patients with advanced CKD.

### Dietary phosphorus restriction

Several studies have examined the effects of dietary phosphate restriction on abnormalities of bone and mineral metabolism, progression of renal dysfunction, and mortality. In patients with advanced CKD, where urinary phosphate excretion is severely impaired, dietary absorption becomes a critical determinant of serum phosphate concentrations. Hemodialysis patients absorb approximately 60% of dietary phosphorus, compared with about 80% absorption in healthy volunteers consuming an identical study meal. The use of activated vitamin D analogs further increases intestinal phosphorus absorption [167].

Since phosphorus exists in virtually all living organisms, it is found in most foods. Dietary sources of phosphorus include the organic phosphorus found in foods high in protein, such as meat, dairy products, eggs, grains, legumes, nuts, and inorganic phosphorus found in food additives and preservatives. Table 23.1 shows a partial list of the phosphorus content in different group of foods.

Any strategy to control dietary phosphorus intake in CKD patients must consider the actual content of phosphorus in food, as well as the bioavailability of phosphorus from various food sources. Organic

**TABLE 23.1** Phosphorus content of selected foods (US Department of Agriculture, (USDA)).

Food	Portion size	P (mg)	Protein (g)	P/protein
Chicken	140 g	286	43	6.65
Turkey	3 oz	208	24	8.7
Beef	3 oz	200	26.4	7.6
Pork	3 oz	224	22	7.4
Veal	3 oz	212	31	6.8
Lamb	3 oz	167	22	7.4
Fish	3 oz	230	20.23	11.36
Crab	3 oz	240	16.5	14.5
Egg (whole)	1 large	99	6.29	15.7
Egg (white)	1 large	5	3.6	1.4
Cheese	1 oz	133	6.6	20
Milk	1 cup	222	7.9	28
Bread	1 slice	25	3.4	7.3
Cereals	1 cup	259	5.2	49.8
Peanuts	1 oz	101	6.7	15.1
Almonds	1 oz	134	6	22.3
Beans	1 cup	183	12	15
Lentils	1 cup	356	17.9	19.9
Rice, white	1 cup	74	4	18.4
Rice, brown	1 cup	162	5	32

phosphorus in animal proteins is hydrolyzed in the intestinal tract and then absorbed into the circulation as inorganic phosphate [168]. Usually, 40%–60% of organic phosphate in animal proteins is absorbed in the gastrointestinal tract. By comparison, plant-derived phosphorus from seeds, legumes, or nuts is less easily absorbed because it is in the form of phytic acid or phytate. Because the human intestine does not secrete phytase, the enzyme required for digestion of phytate and absorption of the phosphorus bound to phytate, the bioavailability of phosphorus from plant-derived food is usually less than 50% [169].

### Inorganic phosphorus and food additives

Phosphorus is the main component of many food additives and preservatives. Phosphorus-containing additives, the most rapidly growing source of dietary phosphorus over the past two decades, are increasingly being added to processed foods, such as enhanced meats, processed or spreadable cheeses, frozen meals, baked products, and beverages. These phosphate salts are used to extend shelf life, to preserve moisture or

color, and to enhance flavor. The phosphate additives found in different preparations (e.g., sodium phosphate, potassium phosphate, calcium phosphate, phosphoric acid, and various pyrophosphates and polyphosphates) are not protein-bound and are more readily available for absorption, being almost 100% absorbed [170,171]. Since 1990, phosphorus-containing food additives in the general US population have doubled and will probably continue to increase as the American demand for convenience and fast food escalates. Depending on individual food choices, phosphorus intake from additives could contribute up to 1 g/day [172,173]. The contribution of inorganic phosphorus from processed foods was determined in an experiment performed with eight graduate students who participated in a randomized, crossover study where two dietary patterns were fed. For one 4-week period, volunteers were fed commercial foods free of phosphate additives; during the second 4-week period, they were fed commercially available foods very similar to those in the control diet, but containing phosphate additives (e.g., processed cheese instead of natural cheese, meats with added phosphates instead of fresh meats, and colas rather than citric acid-containing soft drinks). These substitutions increased the dietary phosphorus intake by an average of 1154 mg/day while keeping the intake of protein and calcium unchanged [174,175].

Soft drink manufacturers add different amounts of phosphate to the beverages to enhance flavor. Many but not all clear-colored beverages or teas are low in phosphate. Table 23.2 shows the phosphorus content of some commonly used beverages [66,176].

Another source of dietary phosphorus which has become increasingly recognized in the literature and may increase the total phosphorus content is the “enhancement” of meat and dairy products. Uncooked meat and poultry products are frequently enhanced

**TABLE 23.2** Phosphate content (mg) of selected beverages (based on 12 oz serving).

Beverage	Phosphate (mg)
Coke	69.9
Pepsi-Cola	57
Diet Cherry Coke	56
Diet Pepsi	50
Dr. Pepper	45
Hires Root Beer	22
Fruitworks	53–140
Gatorade	36
Tropicana Fruit Drinks	37–93

by food processors using sodium and potassium phosphate salts. Enhanced meat and poultry products may increase phosphorus and potassium content by almost two- to threefold, respectively [177]. The federal guidelines require manufactures to include a statement of enhancement with specifications of the additives used, but they are not quantified, and many consumers are not aware that they are purchasing an altered product. Phosphate salts are also used in ham and bacon to improve color and flavor, and to reduce oxidation and stabilize proteins. Different types of cheese contain various amounts of phosphorus, from less than 100 mg (e.g., Brie cheese) to almost 1000 mg per serving of combined organic and inorganic phosphorus in processed soft cheese [20,171,176].

Prescription medications may also be a source of phosphorus that contributes to phosphate intake. In a recent study from a total 1744 drug formulations of 124 different medications, 185 (11%) contained a phosphate salt. Central nervous system (CNS) and CVS medications accounted for 65% and 24% of phosphate-containing medications, respectively. Precisely 30% of Hemodialysis (HD) patients were taking at least one medication that contained phosphate. The median phosphate burden from prescribed medications was 111 mg/day [165]. Some of the multivitamin supplements contain significant amounts of phosphorus (e.g., one Centrum tablet contains 48-mg phosphorus), and it is important to be aware of this when designing a low-phosphorus diet for CKD patients [20]. Therefore care should be taken concerning the phosphate content of drug formulations when prescribing such medications.

Patient education regarding high-phosphorus foods is an important component of the management of hyperphosphatemia. To determine the effect of limiting the intake of phosphorus-containing food additives on serum phosphorus levels among patients with end-stage renal disease, Sullivan et al. assessed 279 patients with elevated baseline serum phosphorus levels greater than 5.5 mg/dL. The intervention group ( $n = 145$ ) received counseling on avoiding foods with phosphorus additives. After 3 months, there was a 0.6 mg/dL decline in the average serum phosphorus level among the educated participants compared with control participants (95% CI,  $-1.0$  mg/dL to  $-0.1$  mg/dL). The authors found that counseling patients with ESRD to avoid phosphorus-containing food additives resulted in a modest but clinically significant improvement in serum phosphorus levels [178].

The Food and Drug Administration requires products to include a nutrition facts label that lists the content of several important nutrients, including calories, cholesterol, sodium, protein, and calcium. However, many nutrition labels fail to list the phosphorus content, making it difficult for patients to know how much

phosphorus they are ingesting. In one study, Sullivan and colleagues found that phosphorus content was not listed on any of 38 representative chicken products purchased in grocery stores even though 92% of these products contained phosphorus additives [179].

Educating dialysis patients to limit their intake of additive-containing food products constitutes an important dietary recommendation. However, following such recommendations can be challenging for multiple reasons. The availability of additive-free products in grocery stores may be limited. Additive-free products are more expensive and require more effort to prepare, which may represent a serious limitation for dialysis patients with physical or social challenges. In addition, ingredient lists are generally not present on fast food items, making it difficult to identify phosphorus-containing additives. Simply knowing that a product contains a phosphorus additive does not allow an accurate estimate of its phosphorus content.

There is a need for labeling changes, and hopefully in the future the policymakers will mandate that phosphorus content of foods must be included on the nutrition facts label. This will encourage manufacturers to limit the use of phosphorus additives, will help patients limit their phosphorus intake, will guide providers to better instruct patients, and will help care providers and researchers to accurately assess dietary intake.

### Dietary phosphorus, protein intake, and phosphorus—protein ratio

Foods rich in protein are an important source of dietary phosphorus. Thus dietary restriction of phosphorus is frequently associated with a decrease in dietary protein intake. This can lead to malnutrition and protein-energy wasting, important risk factors for death in maintenance dialysis patients [180]. A 3-year study of 30,075 prevalent maintenance hemodialysis patients showed that a decrease in serum phosphorus that was occurred with a concomitant decrease in protein intake increased the risk of death. The patients whose serum phosphorus decreased and whose normalized protein equivalent of total nitrogen appearance (nPNA) increased over 6 months had greater survival, with a case mix-adjusted death risk ratio of 0.90 (95% confidence limits: 0.86, 0.95;  $P < .001$ ). In contrast, those whose serum phosphorus increased but whose nPNA decreased or those whose phosphorus and nPNA both decreased had worse mortality with risk ratio of 1.11 (1.05,1.17;  $P < .001$ ) and 1.06 (1.01,1.12;  $P = .02$ ), respectively. The authors concluded that the risk of controlling serum phosphorus by restricting dietary protein intake may outweigh the benefit of controlling phosphorus and may lead to greater mortality [181].

Noori et al. conducted a cohort study in 224 maintenance hemodialysis patients to examine the survival predictability of dietary phosphorus and the ratio of dietary phosphorus (in mg) to protein intake (in g). Both higher phosphorus intake and a greater dietary phosphorus to protein ratio were associated with increased death risk in hemodialysis patients, even after adjustments for serum phosphorus, type of phosphate binder used, and dietary protein, energy, and potassium intake [182]. The ratio of dietary phosphorus to protein may represent a better dietary phosphorus metric for CKD patients. The metric phosphorus to protein ratio is also recommended by the KDOQI guidelines.

There is a great variation in the ratio of phosphorus to protein among different protein sources. Low phosphorus-to-protein ratios are found in nondairy animal-derived foods, including egg whites, while whole eggs, dairy products, legumes, and fast foods have higher phosphorus-to-protein ratios. Egg whites are an excellent source of high-quality protein, with a low phosphorus-to-protein ratio and a low-cholesterol content. Taylor et al. conducted a pilot dietary intervention study in 13 hemodialysis patients who substituted pasteurized liquid egg whites for meat at one meal per day. Serum phosphorus level decreased significantly by 0.9 mg/dL over 6 weeks, while serum albumin level tended to increase. Pasteurized liquid egg white products were well tolerated and may become an important dietary protein source for CKD patients [183].

Sherman and his colleagues measured the phosphorus and protein content of 44 food products, including 30 refrigerated or frozen precooked meat, poultry, and fish items, using the Association of Analytical Communities official method. The authors found that the ratio of phosphorus to protein content ranged from 6.1 to 21.5 mg of phosphorus per 1 g of protein. The mean ratio was 14.6 mg/g in the 19 food products with a label listing phosphorus as an additive compared with 9.0 mg/g in the 11 items without listed phosphorus [184]. For example, whey protein has a low phosphorus-to-protein ratio, making it an excellent source of protein supplementation, without worsening of hyperphosphatemia [185].

In addition to the phosphate content of a food, measures targeting a decrease in phosphorus levels should also depend upon an understanding of the ability to absorb phosphorus within the gastrointestinal tract. In contrast to highly bioavailable phosphorus additives, plant-derived phosphorus is less well absorbed by humans. One of the few studies done on the absorbability and metabolic consequences of dietary phosphorus from different food sources involved 16 young Finnish females who were fed five experimental diets: a control diet that contained 500 mg of phosphorus, and four diets containing the same amounts of

phosphorus (~1500 mg), but from different sources, such as meat, cheese, whole grains, or phosphate supplements. Each diet was consumed for 1 day, during which time serum levels of phosphate and 24-hour urinary phosphate excretion were measured. Based on serum phosphorus and urinary phosphate excretion, phosphorus contained in meat, cheese, and supplements appeared to absorb better than phosphorus from whole grains, suggesting lower intestinal absorption of phosphorus with the grain-based diet. Moe et al. conducted a crossover trial in nine patients with CKD stage 3 or 4 (estimated GFR 25–40 mL/min) and normal serum phosphorus to directly compare a grain-/soy (vegetarian)-based protein diet to a meat-/dairy (meat)-based protein diet with equivalent nutrients. The study demonstrated that 7 days of the vegetarian diet resulted in lower serum phosphorus levels, decreased FGF-23 levels, and a trend toward decreased 24-hour urinary phosphorus excretion [186].

In conclusion, renal patients should be educated on how to substitute protein sources with high phosphorus bioavailability, such as enhanced meats, processed cheese, or fast food, with sources that have low phosphorus bioavailability, such as whole-grain and unprocessed foods [187,188]. While changing the therapeutic approach to decrease the amount of foods that are high in phosphorus additives and/or that have a high phosphorus-to-protein ratio seems to help control the phosphorus, more human studies are needed to support the efficacy of these approaches.

## Phosphate removal with dialysis

Phosphate is unevenly distributed throughout the body, being predominantly localized in the intracellular space. Hence, most phosphate removed during dialysis is derived from the intracellular space. The kinetics of phosphate removal differ significantly from classic urea kinetics. During the first phase of dialysis, there is a rapid decline in serum phosphate levels due to phosphate removal from the extracellular space. This is followed by a second phase during which phosphate removal continues but at a lower rate, but plasma phosphate level does not further decline, as a consequence of phosphate mobilization from a pool other than the extracellular fluid. The rate of change in plasma phosphate levels is most likely determined by the rate of phosphate transfer from one or more intracellular compartments to plasma compartment. A large rebound of phosphate occurs within a couple of hours after termination of dialysis, reaching about 80% of predialysis values [189–191].

Phosphate removal varies among the different modalities of dialysis. With conventional, thrice-weekly

hemodialysis (4 hours), phosphate removal ranges from 600 to 900 mg per treatment (1800–2700 mg/week). Conventional hemodiafiltration improves phosphate removal (1170 mg per treatment), but overall, conventional, thrice-weekly intermittent hemodialysis is largely inadequate for the elimination of the total amount of phosphate absorbed from the intestinal tract in 1 week (4000–5000 mg) from a standard protein intake [192,193]. In short daily hemodialysis the amount of phosphate removal depends on session length and frequency of sessions. A study by Ayus et al. compared 51 patients treated with conventional hemodialysis (three sessions/week of 4 hours each) with 26 patients treated with short daily hemodialysis (six sessions/week of 3 hours each). There was a significant decrease in serum phosphate levels in patients on short daily hemodialysis from a baseline of  $6.26 \pm 2.57$ – $4.58 \pm 1.06$  at 6 months ( $P < .0001$ ) and  $4.20 \pm 1.16$  at 12 months ( $P < .0001$ ), compared with conventional thrice-weekly hemodialysis, where serum phosphate was  $4.98 \pm 1.49$  at baseline and  $5.02 \pm 1.14$  at 12 months. In 70% of patients in the short hemodialysis group phosphate binders were discontinued by the end of the study period. They also found that serum phosphate levels were independently associated with a reduction in left ventricular mass index, likely through increases in vascular compliance [194].

Phosphate is effectively removed with nocturnal hemodialysis. Mucsi et al. compared eight patients on conventional hemodialysis (three sessions per week of 4 hours each) with eight patients on nocturnal hemodialysis (six sessions per week of 8 hours each). The weekly phosphate removal was more than twice with nocturnal hemodialysis as compared to conventional hemodialysis, with significantly lower average serum phosphate levels in the nocturnal hemodialysis group (4 vs 6.5 mg/dL) [195]. Similar results were obtained in a study comparing patients undergoing conventional three-times weekly hemodialysis with hemodialysis sessions of extended duration that were adjusted to provide a similar eKT/V(urea), phosphate removal was 40% higher with extended hemodialysis as compared to conventional hemodialysis. Interesting, although hourly mass removal of phosphate was higher during conventional hemodialysis, the prolonged lower rate of phosphorus removal that was conducted for a longer period of time led to a higher phosphate removal in the extended hemodialysis period [196].

Another randomized trial involved 52 patients who were assigned to receive nocturnal hemodialysis six-times weekly or conventional hemodialysis three-times weekly. In the nocturnal hemodialysis group, the average predialysis serum phosphate levels were reduced from  $5.5 \pm 1.5$  to  $4.4 \pm 1.7$  mg/dL, and phosphate binders were reduced or discontinued in 73% of the patients [197]. Incenter, three-times weekly nocturnal

hemodialysis has been shown to improve phosphate management. Bugeja et al. reported their results in 39 patients who were switched from three-times weekly conventional hemodialysis to three-times weekly incenter nocturnal hemodialysis. After conversion to incenter nocturnal hemodialysis, median phosphate levels decreased from 5.9 to 3.7 mg/dL, and the mean daily dosage of phosphate binders declined from 6.2 to 4.9 pills/day at study end [198]. Interestingly, in a recent study that analyzed phosphate removal during hemodialysis, it was observed that phosphate removed during the first hour corresponded to 25% of the total phosphate removed, and that most of the phosphate was removed during the rest of the procedure [199]. The authors suggested that in patients receiving more frequent nocturnal hemodialysis, lower phosphate levels are attained not because phosphate is removed during the first 1–2 hours of hemodialysis, but because it is performed more frequently.

In conclusion, hemodialysis removes phosphorus, but its typical regimen of three times per week, together with dietary phosphate restriction, is usually not enough to control serum phosphorus levels. Increasing the length and frequency of HD improves phosphate removal and may be enough to control hyperphosphatemia, but application of this type of regimen in a large scale may be impractical and too costly.

Many peritoneal and intrinsic factors influence phosphate transport and clearance during peritoneal dialysis. Weekly average phosphate removal in patients on continuous ambulatory peritoneal dialysis (CAPD) has been reported to be around 70 mmol (2170 mg) with  $4 \times 2$  L exchanges per day and 105 mmol (3250 mg) with  $4 \times 3$  L exchanges per day [200]. Peritoneal phosphate clearance is lower than the clearance of small water-soluble substances. Some studies show that peritoneal phosphate clearance correlates better with creatinine clearance than with urea removal [201,202]. In a retrospective study that involved 129 peritoneal dialysis patients, there was a strong correlation between peritoneal phosphate and creatinine clearance. In the multivariate regression analysis, peritoneal phosphate clearance was independently associated with peritoneal creatinine clearance and not with Kt/V urea. This suggests that peritoneal creatinine clearance can be used as a surrogate marker for peritoneal phosphate clearance [201].

Peritoneal phosphate clearance is influenced by the different peritoneal dialysis modalities and across different peritoneal membrane transport characteristics. For patients in the high transport category, no difference in phosphate clearance is observed between CAPD and continuous cyclic peritoneal dialysis (CCPD). For patients in the high average, low average, and low transport category, peritoneal phosphate clearance is

higher with CAPD than with CCPD, whereas creatinine clearance does not differ. These results suggest that in high average, low average, and low transporters, peritoneal phosphate clearance may be increased by increasing cycle dwell times, and by increasing the number of exchanges for high transporter patients. All patients may benefit from increased convective peritoneal phosphate clearances through higher ultrafiltration rates. However, there are no available studies on the effect of increased ultrafiltration rates on peritoneal phosphate clearance [201,203].

In conclusion, weekly phosphate removal by the usual dialysis treatments is inadequate in comparison to the usual weekly dietary phosphate intake, and additional therapy may be required to maintain desirable serum phosphate levels. Many CKD patients and the majority of chronic dialysis patients require administration of oral phosphate binders to control serum phosphate.

### Aluminum binders

Aluminum hydroxide, an effective phosphate binder, was the binder of choice for many years, but due to the gradual tissue accumulation of absorbed aluminum, long-term use of this binder was found to be associated with cognitive disturbances, osteomalacia, refractory microcytic anemia, and myopathy [204–208]. There is no evidence to suggest that even low levels of exposure to aluminum is safe for chronic use of this binder.

### Calcium-based binders

Calcium acetate and calcium carbonate are inexpensive and effective in controlling hyperphosphatemia. However, there is increasing concern that they cause positive calcium balance, vascular calcification, and CVS mortality in patients with advanced CKD [18,132,209,210]. Calcium carbonate has poor solubility in a nonacid environment, which is required for optimal calcium phosphate binding, and many patients with severe renal failure have achlorhydria or are taking H<sub>2</sub>-blockers or proton pump inhibitors (PPIs). Calcium acetate, on the other hand, is more soluble at a higher pH. Several studies have found calcium acetate to be more effective than calcium carbonate at binding intestinal phosphate per mmol of administered elemental calcium. The clinical significance of this effect is unclear, with a few studies reporting equivalent rates of hypercalcemia [211–213]. Hypercalcemia is most likely to occur when these binders are used in combination with a vitamin D analog. Long-term use of calcium-based phosphate binders may contribute to soft tissue and vascular calcification. They can

also result in oversuppression of PTH and the development of a dynamic bone disease [139,214,215]. As a consequence, noncalcium-based phosphate binders have been developed and are increasingly used to control phosphate absorption without causing a calcium burden. These agents include sevelamer, lanthanum carbonate, magnesium, and iron-based agents. However, controversy still exists regarding the effects of these binders on calcium balance, vascular calcification, and mortality as discussed in the next sections.

### Sevelamer

Sevelamer hydrochloride and sevelamer carbonate are nonaluminum, noncalcium phosphate-binding polymers that bind phosphate through ion exchange. Since sevelamer carbonate does not decrease serum bicarbonate levels, it may be more appropriate for patients at risk for metabolic acidosis. The two agents appear to be equivalent in their ability to control serum phosphate levels. This was demonstrated in a double-blind, randomized study of 79 hemodialysis patients, who were randomly assigned to either sevelamer carbonate or sevelamer hydrochloride for 8 weeks, followed by a crossover to the other regimen for an additional 8 weeks of treatment. Sevelamer carbonate and sevelamer hydrochloride were equivalent in controlling serum phosphorus, while serum bicarbonate levels increased with sevelamer carbonate [216–218]. Many clinical studies have shown that sevelamer is effective in lowering serum phosphate levels and is generally well tolerated. Furthermore, sevelamer binds bile acids, decreases fecal bile acid excretion, and lowers Low Density Lipoprotein (LDL) cholesterol [216,219–221].

Several randomized clinical trials that compared sevelamer and calcium salts demonstrated similar phosphate-lowering abilities [151,222,223]. Unfortunately, the designs of these studies have been heterogeneous in patient selection, duration of follow-up, and outcome measures, making comparisons between studies difficult to interpret. In the prospective Treat-to-goal (TTG) Trial [152], 200 hemodialysis patients were assigned to receive sevelamer or a calcium-based phosphate binder. At 1 year, sevelamer and calcium-based binders provided equivalent control of serum phosphate levels ( $5.1 \pm 1.2$  vs  $5.1 \pm 1.4$  mg/dL, respectively), but serum calcium concentrations were significantly higher in the calcium-treated group ( $P = .002$ ). The use of sevelamer was also associated with a lower incidence of hypercalcemia (15% vs 16%) and a decreased incidence of low PTH levels (30% vs 57%). Other randomized clinical studies conducted to compare sevelamer to calcium-based binders showed beneficial effects of sevelamer on

biochemical parameters, including C-reactive protein, LDL cholesterol, uric acid, fetuin-A, and FGF-23. Whether these potential treatment benefits with sevelamer lead to more favorable clinical outcomes is yet to be determined [80,224–226].

The results of the studies on progression of vascular calcification with sevelamer versus calcium-based phosphate binders have been contradictory. In the TTG trial, the median percentage change in CAC score from baseline was significantly greater with calcium-based binders than with sevelamer at both 26 weeks (14% vs 0%,  $P = .002$ ) and 52 weeks (25% vs 6%,  $P = .04$ ) [152]. The Renagel in New Dialysis (RIND) was a prospective, randomized study that compared the effect of sevelamer and calcium-based binders on the progression of vascular calcification in 129 incident hemodialysis patients. Subjects treated with calcium-based phosphate binders showed more rapid and more severe increases in CAC score when compared with those receiving sevelamer hydrochloride ( $P = .056$  at 12 months,  $P = .01$  at 18 months) [151]. By comparison the Calcium Acetate Renagel Evaluation 2 trial was a noninferiority trial designed to compare the effects of sevelamer and calcium-based phosphate binders on progression of coronary artery calcification in hemodialysis patients. After 12 months of therapy, no significant difference was observed in progression of the coronary artery calcification between these two groups. The study was limited by its short duration, substantial drop-out rates, and the inclusion of a higher proportion of diabetic patients [226]. The same effects of treatment on coronary artery calcification were found in the Phosphate Binder Impact on Bone Remodeling and Coronary Calcification study where 101 hemodialysis patients were assigned to sevelamer or calcium acetate. Due to the inconsistencies among these study results, larger studies will be needed to determine the effect of sevelamer on vascular calcification [226–228].

Studies comparing mortality with phosphate binders are controversial. A few studies evaluated mortality rates with sevelamer versus calcium-based phosphate binders. In a post hoc analysis of the RIND study, mortality rate at a median follow-up of 44 months was higher in calcium-treated patients (10.6/100 patient years, 95% CI 6.3–14.9) than in sevelamer-treated patients (5.3/100 patient years, 95% CI 2.2–8.5;  $P = .05$ ). With multivariate analysis, there was a greater risk of death for patients treated with calcium-based phosphate binders (HR 3.1, CI 1.23–7.61;  $P = .016$ ) [146]. The Dialysis Clinical Outcomes Revisited study enrolled 2103 hemodialysis patients who were assigned to treatment with either sevelamer hydrochloride or calcium (70% to calcium acetate and 30% to calcium carbonate) [223]. The primary analysis showed no significant difference in all cause

and cause-specific mortality between the two groups (HR with sevelamer, 0.93; 95% CI, 0.79–1.10). However, there was a significant age interaction as only in the patients who were greater than 65 years old; there was an effect of sevelamer on lowering mortality rate. Criticisms of this study include a high rate of loss to follow-up, long-time undergoing dialysis treatment and high percentage of diabetics [229–231]. Several metaanalyses have addressed these aspects. In one of them the results of five randomized trials consisting of 2429 patients showed a similar risk difference for all-cause mortality between sevelamer hydrochloride and calcium-based agents (risk difference,  $-2\%$ ; 95% CI,  $-6$ – $2$ ) [232]. More recent metaanalysis of randomized trials comparing noncalcium versus calcium-based binders on mortality showed that patients treated with noncalcium binders had a 22% reduced mortality compared to those assigned to calcium-based phosphate binders [233]. In another metaanalysis of randomized controlled trials of patients with CKD stages 3–5 and patients on dialysis treated with calcium-based binders compared with sevelamer, patients treated with sevelamer had lower all-cause mortality, but no significant difference in CVS mortality was observed. In addition, in the group treated with sevelamer the risk of hypercalcemia was lower and PTH levels were higher. Serum phosphate levels were not significantly different between groups [229]. In most of the studies, combined gastrointestinal side effects occurred more often with sevelamer.

In conclusion, although controversy still exists about the possible benefits of sevelamer compared with calcium-based phosphate binders [234,235], the majority of randomized studies suggest that calcium-based binders and sevelamer are similarly effective at lowering phosphate. However, sevelamer is associated with less CVS or all-cause mortality and a lower risk of hypercalcemia and CAC. These aspects and the cholesterol-lowering effect of sevelamer should be considered when choosing a phosphate binder in patients with high CVS risk.

## Lanthanum

Lanthanum carbonate is another phosphate binder able to bind phosphate across a wide pH range. Short-term trials demonstrate the efficacy of lanthanum carbonate in lowering serum phosphate levels, reducing iPTH, and potentially decreasing FGF-23 levels [236–239]. Clinical studies that compared lanthanum with other phosphate binders mainly evaluated their effects on biochemical parameters and on bone histology. Lanthanum and calcium-based phosphate binders appear to be similarly effective in reducing serum phosphate concentrations in patients with end-stage renal disease. In the largest trial the proportion of

patients who had documented episodes of hypercalcemia was significantly smaller among the patients receiving lanthanum (4.3%) than among those receiving standard care, in the majority of cases, with calcium-based phosphate binders (8.4%) [240,241].

There has been concern about the possibility of lanthanum given the past experience with aluminum-based phosphate binders [242]. However, the pharmacodynamics of lanthanum are different than that of aluminum, and there has not been demonstrated the accumulation of lanthanum in the CNS. With respect to bone, in a study of patient receiving lanthanum carbonate compared to standard therapy for over 2 years, phosphate control was similar in the two groups, but those receiving lanthanum carbonate showed higher bone turnover after 1 year and higher bone volume after 2 years with lanthanum carbonate [243].

Comparative studies of lanthanum carbonate and calcium-based binders with sevelamer are limited. In a preliminary study of chronic dialysis patients followed for 3 years, lanthanum carbonate and calcium carbonate yielded similar results in terms of effectiveness as phosphate binders, and no statistically significant differences were observed in terms of CVS mortality [244]. Similarly, there were no statistically significant difference in serum PTH levels between the two groups. Side effects of lanthanum carbonate are particularly gastrointestinal. Thus patients may find the lanthanum carbonate pills difficult to swallow, as the tablets require crushing or breaking into smaller pieces.

### Newer phosphate binders

In recent years, newer phosphate binders have entered the market for use in chronic dialysis patients. These include, iron-based products, and magnesium salts. Ferric citrate and sucroferric oxyhydroxide bind phosphate in the intestine and reduce serum phosphate levels. A randomized study comparing ferric citrate with sevelamer and calcium-based binders shows effective serum phosphate control. Calcium and PTH levels were not different between groups. In addition, ferric citrate increased iron stores and decreased requirements for intravenous iron and erythropoietin-stimulating agents while maintaining hemoglobin levels [245,246]. Based on these properties, ferric citrate is also approved as an iron replacement product for the treatment of iron deficiency anemia in adult CKD patients not treated with dialysis [247]. However, gastrointestinal effects and pill burden are frequent limitations of ferric citrate while sucroferric oxyhydroxide requires chewing or crushing before ingestion.

In conclusion, the evidence available favors a benefit of controlling serum phosphate levels in CKD, particularly

in advanced CKD. All phosphate binders currently in use are similarly effective at reducing serum phosphate levels. Nevertheless, hyperphosphatemia continues to be a frequent problem in CKD patients. In addition, phosphate binders are not devoid of side effects that in many cases limit their use. Ideally, the choice of the binder should be based on its capacity to adequately control serum phosphate levels while minimizing side effects, and particularly vascular calcification. In many cases, single approaches are not sufficient to maintain phosphate levels within the normal range. As suggested by KDIGO guidelines [2], phosphate-lowering measures should be used in concert to control hyperphosphatemia in a patient-oriented approach. These measures include diet, phosphate binders, and adequate dialysis. In addition, as will be discussed in the next sections, in patients with SHPT, reduction of PTH levels is important as PTH actions on bone results in bone resorption and release of phosphate which, in turn, increases serum phosphate levels independent of intestinal absorption.

Noncalcium binders should be the preferred binders due to the data associating calcium-based binders with CVS and all-cause mortality, and vascular calcification, particularly in those patients at higher risk of vascular calcification. In this regard the KDIGO guidelines suggest restricting the dose of calcium-based phosphate binders in patients with CKD G3a-G5D receiving phosphate-lowering treatment (2B). However, noncalcium binders are more expensive, an important concern in health-care systems that have lower insurance coverage. Gastrointestinal side effects and a higher pill burden are more frequent with noncalcium binders. Finally, the effects of phosphate binders on clinical outcomes remain controversial. Thus more placebo-controlled studies are necessary to more definitively examine whether the reduction of serum phosphorus by phosphate binders improves clinical outcomes.

### Therapy with vitamin D sterols

Because the decrease in calcitriol production plays an important role in the development and maintenance of SHPT, the use of vitamin D sterols represents an important part of the treatment of hyperparathyroidism in CKD patients. Vitamin D sterols suppress PTH secretion, increase the absorption of both calcium and phosphorus from the gut, and appear to be associated with a survival advantage in chronic hemodialysis and CKD patients [248–250]. There are six active vitamin D derivatives currently available: calcitriol, alfacalcidol, doxercalciferol, 22-oxacalcitriol, falecalcitriol, and paricalcitol. In the United States the available agents include calcitriol, paricalcitol, and doxercalciferol.

Calcitriol is the natural form of active vitamin D produced by the human body and was the first vitamin D agent used for the treatment of hyperparathyroidism. Early studies with calcitriol in experimental animals as well as in clinical studies suggested that intermittent intravenous calcitriol was more effective and better tolerated than oral calcitriol. This was thought to be due to greater delivery of the vitamin D metabolite to peripheral target tissues other than the intestine [251]. Subsequent studies have shown that both intermittent oral and intravenous bolus therapy were equally effective with regard to PTH suppression and the side effects of treatment [252].

The vitamin D analog, paricalcitol, was introduced and developed to obtain a more selective suppressive action on the parathyroid gland while minimizing the propensity of vitamin D sterols to cause hypercalcemia and hyperphosphatemia. In experimental animals, paricalcitol was effective in suppressing PTH while inducing less hypercalcemia and hyperphosphatemia than calcitriol [253]. However, direct head-to-head randomized studies in patients are limited. A double-blind, randomized, multicenter study compared the safety and effectiveness of intravenous paricalcitol and calcitriol in suppressing serum PTH concentrations among 263 hemodialysis patients. The primary end point was greater than 50% reduction in baseline PTH, and the secondary end points were the occurrence of hypercalcemia and an elevated serum CaxP product. Paricalcitol treatment reduced PTH concentrations more rapidly with fewer sustained episodes of hypercalcemia or an increased CaxP product than calcitriol therapy [254].

Doxercalciferol, a prohormone that is hepatically activated into a VDR agonist, has similar efficacy compared to paricalcitol, albeit larger doses are required for PTH suppression. Studies with oral and intravenous formulations of doxercalciferol showed that both preparations are well tolerated and able to lower plasma PTH, with less frequent hypercalcemia seen with intravenous treatment [255].

Although the effectiveness of active vitamin D analogs in controlling SHPT has been demonstrated in multiple studies, particularly with regard to biochemical endpoints in patients with CKD 3–5 and in ESRD patients on dialysis [254,256], relatively few studies have examined their effect on bone histomorphometry [257,258]. Therefore more studies are required to evaluate the effect of these agents on bone and other organs. In this regard, KDIGO guidelines suggest that in adult patients with CKD G3a–G5 not on dialysis calcitriol and vitamin D analogs not be routinely used (2C), and that it is reasonable to reserve the use of calcitriol and vitamin D analogs for patients with CKD G4–G5 with severe and progressive hyperparathyroidism (not graded). However, it has been claimed that there is ambiguity in this guideline because the term

“severe” is not defined [259]. In patients with CKD 5D, KDIGO guidelines suggest PTH-lowering therapy with calcitriol or vitamin D analogs (2B) [2]. Hypercalcemia and excessive suppression of PTH are the main concerns with this type of therapy.

Another limitation of active vitamin D analogs is their limited capacity to reduce serum PTH levels to appropriate values, particularly in patients with severe SHPT with nodular hypertrophy in whom VDR expression in the parathyroid cells are decreased or downregulated. In these cases the use of other agents alone or in combination with vitamin D analogs may be required.

Low serum levels of 25(OH) vitamin D are a frequent finding in CKD patients. Since 25(OH) vitamin D is the substrate for calcitriol, it seems logical to correct vitamin D deficiency or insufficiency by providing cholecalciferol or ergocalciferol, the natural forms of vitamin D, as a mean to increase calcitriol levels. However, suppression of PTH secretion with native vitamin D to control SHPT may not be sufficient, and the use of active vitamin D analogs or other PTH lowering agents is often required. Nevertheless, native vitamin D continues to be used in CKD patients because other actions in addition to the treatment of SHPT may be beneficial to the patient [82].

Studies have shown that calcifediol, a vitamin D prohormone, is safe and effective for treating SHPT and vitamin D insufficiency in patients with CKD stage 3 or 4 [260]. More studies are needed to examine in more detail the effects of calcifediol on end organs.

## Calciomimetics

The CaSR in the parathyroid gland plays a central role in the management of SHPT. This receptor, highly sensitive to changes in calcium concentrations, also responds to other substances known as calciomimetics that can act allosterically as modulators of PTH secretion. Natural calciomimetics, such as magnesium and other inorganic compounds, act directly at the CaSR in the parathyroid gland and decrease PTH secretion (calciomimetics type I). Calciomimetics type II [261] bind to a site different from the physiological ligand, increasing the sensitivity of the CaSR, which results in the inhibition of PTH secretion at lower calcium concentrations [261,262]. Several prospective randomized studies in chronic dialysis patients with hyperparathyroidism have found that the calciomimetics produce a dose-dependent reduction in the plasma PTH concentrations and a decrease in the serum calcium and phosphate levels [263–266]. Cinacalcet, a compound used daily and orally, is the calciomimetic most extensively used for the treatment of SHPT [96,262–264]. More recently, etelcalcetide, a new generation of calciomimetics, is increasingly

used [267]. This compound is used intravenously and due to its longer metabolism, it is administered three times a week during dialysis. Several randomized controlled trials have demonstrated the efficacy of these compounds at decreasing PTH levels [268,269]. Calcimimetics also decrease serum calcium and phosphorus levels [267–270]. The effectiveness of cinacalcet has been demonstrated in patients who did not achieve adequate PTH control because of their elevated serum calcium and phosphate levels while they received therapy with active vitamin analogs [263]. In contrast to cinacalcet, etelcalcetide may activate the CaSR even in the presence of hypocalcemia, and its longer half-life confers the advantage that it can be administered only three times a week at the end of a hemodialysis session. In patients on hemodialysis with moderate-to-severe SHPT who were randomized to etelcalcetide or cinacalcet for 26 weeks, patients given etelcalcetide were more likely to attain a reduction of PTH greater than 30% compared to the cinacalcet group [268]. Etelcalcetide also demonstrated noninferiority compared with cinacalcet and, in fact, was superior at achieving control of serum PTH levels. More patients in the etelcalcetide group achieved more than 50% reduction in PTH levels compared to patients in the cinacalcet group. The number of patients receiving calcium-based phosphate binders or higher calcium concentration in the dialysate increased in both groups, and side effects were not different.

Prospective randomized studies have shown that cinacalcet diminishes bone fractures [271]. Studies of bone histology also show that treatment with cinacalcet, in addition to decreasing serum PTH levels, improves bone histological parameters of hyperparathyroidism, particularly bone turnover and fibrosis, indicating improvement in parathyroid-associated bone disease. Adynamic bone disease, frequently associated with PTH over suppression, was observed in a few patients treated with cinacalcet [272–274]. In one study, one patient, who had overt hypophosphatemia at baseline that reoccurred during follow-up, developed osteomalacia. This patient also had PTH oversuppression while taking cinacalcet [272]. These studies demonstrate an end-organ effect of cinacalcet in controlling the bone disorders in SHPT. However, close follow-up is required of patients treated with cinacalcet or etelcalcetide, particularly with regard to the magnitude of changes in their serum PTH, because oversuppression of PTH may lead to low bone turnover disease.

The ADVANCE trial was a prospective, randomized, controlled trial designed to evaluate the effects of cinacalcet plus low-dose vitamin D on vascular and cardiac valve calcification in 360 prevalent adult hemodialysis patients. The results of the study showed that

coronary artery calcifications and valvular calcifications were significantly lower in the cinacalcet plus low-dose vitamin D group than the vitamin D sterol alone group [275].

One of the most common side effects seen with calcimimetics is hypocalcemia, thought to occur after decreased mobilization of calcium from bone caused by reduced PTH levels. This can be managed by adjustments in calcium-based phosphate binders, reductions in cinacalcet dose, or using these maneuvers combined with low doses of vitamin D sterols in patients with moderate-to-severe hyperparathyroidism [276].

Some of the main concerns regarding the treatment of SHPT with PTH-lowering agents relate to the desired magnitude of reduction of serum PTH levels, when to start and when to stop treatment with PTH-lowering agents, and what agent or combination of treatments should be employed. One major limitation of treatment guidelines is that at present, the histomorphometric analysis of the bone continues to be “gold standard” for an effective diagnosis of the bone alterations in CKD. However, on clinical grounds, this application is very limited because it is invasive, requires expert analysis of the bone histology, is costly, and is difficult to apply on a large scale.

Several studies have attempted to establish a relationship between the type of bone disease and serum biochemical markers. The KDIGO and KDOQI workgroups and other organizations suggest ranges of serum PTH levels to be achieved in CKD patients. KDOQI guidelines suggest a serum PTH range of 150–300 ng/mL as the optimal limit to avoid low or high turnover [277]. Similarly, since PTH levels may vary with different assays used in clinical laboratories (see earlier), the KDIGO guidelines in 2009 suggested a serum PTH range between two and nine times the highest normal value for the PTH assay used, but very few studies have addressed this issue directly [1]. Because bone turnover is mainly a function of the degree of hyperparathyroidism, serum PTH levels have been used as a surrogate indicator of bone turnover. Intact PTH (iPTH) has been studied for the diagnosis of bone turnover in dialysis patients and, together with serum calcium, phosphorus, and total alkaline phosphatases or bone-specific alkaline phosphatase, is frequently used to guide the pharmacologic treatment of CKD-MBD.

Other bone biomarkers have been evaluated for their predictive value in assessing renal osteodystrophy, but results have been inconclusive. Furthermore, some studies have shown that in a high proportion of dialysis patients, bone turnover cannot be accurately predicted from serum PTH levels [278]. A cross-sectional retrospective study of 492 chronic dialysis patients from four different countries examined the

accuracy of biochemical markers to predict bone histopathology. Serum PTH and alkaline phosphatase allowed the discrimination of low bone turnover from nonlow bone turnover, and high from nonhigh bone turnover [260]. The combination of these two markers offered a minimal additional degree of discrimination. The best PTH cutoff to discriminate low from nonlow bone turnover, bone formation rate per unit bone surface, (BFR/BS) was 103.8 pg/mL, whereas the best serum PTH cutoff to discriminate high from nonhigh bone turnover was 323.0 pg/mL. Similarly, the best cutoff for bone-specific alkaline phosphatase was 33.1 U/L for low from nonlow turnover, and 42.1 U/L for high bone turnover. These results indicate that serum iPTH, with some certainty, can be used to discriminate low bone turnover from high bone turnover, and these PTH values are consistent with the recommendations of both, KDOQI and KDIGO. These results also provide reasonable help regarding the questions of when to start and when to stop treating high bone turnover disease in dialysis patients. Therefore at present serum PTH, although with limitations, continues to be the most accurate discriminator between high and low bone turnover disease in patients in dialysis. However, it should be taking into account that bone turnover is not the only marker of bone disease in CKD and that markers for other known bone alterations in renal osteodystrophy have not been evaluated.

### Parathyroidectomy

The availability of effective PTH-lowering agents has made parathyroidectomy less necessary. However, this is still an alternative method for some patients, especially those with severe SHPT with nodular hyperplasia, difficult to control by medical means [2]. Parathyroidectomy may be indicated in these latter patients who become hypercalcemic or hyperphosphatemic, which precludes treatment with active vitamin D analogs, or in patients in whom calcimimetics cannot control very high levels of serum PTH. Parathyroidectomy should also be considered in patients with severe SHPT and metastatic calcification or calciphylaxis.

Total parathyroidectomy with autotransplantation of parathyroid tissue in the forearm or subtotal parathyroidectomy is the procedure most frequently utilized. In a study performed in 1992, excellent results were reported with both procedures; however, satisfactory long-term control of parathyroid gland function was achieved in only one-third of the patients; the other two-thirds remained either hypoparathyroid or developing recurrent hyperparathyroidism [279]. Hypoparathyroidism after renal transplantation may be associated with hypercalciuria with nephrocalcinosis and renal failure.

Other complications of parathyroidectomy include recurrent laryngeal nerve palsy, persistent hyperparathyroidism, hypoparathyroidism, and hungry bone syndrome. Nevertheless, parathyroidectomy is a relatively safe procedure. In a recent study from a national database in the Netherlands of patients with ESRD-related hyperparathyroidism who underwent parathyroidectomy and kidney transplantation between 1994 and 2015, 13 patients (7.0%) required reexploration for persistent or recurrent disease, and 30-day mortality and complication rates were 0.0% and 7.9%, respectively [280]. When hyperparathyroidism recurs in dialysis patients, medicinal treatment to lower serum PTH can often be used, depending on the level of PTH. In some patients treated with total parathyroidectomy with the implantation of parathyroid tissue in the forearm, further surgery may be necessary to remove excess parathyroid tissue, or to explore for additional parathyroid glands in the neck. Conversely, hypoparathyroidism with hypocalcemia, which persists despite treatment with large doses of vitamin D and calcium, can be treated with recombinant PTH (teriparatide).

### Conclusion

Disorders of bone and mineral metabolism begin early in the course of declining renal function and progress steadily as kidney function deteriorates. Numerous studies have shown a close relationship between SHPT and poor clinical outcomes. These include bone fracture, CVS morbidity and mortality, as well as all-cause mortality. Although studies demonstrating a causal relationship between disordered bone and mineral metabolism in CKD and clinical outcomes are still limited, knowledge of the pathophysiology of these alterations has led to important therapeutic strategies to correct the abnormalities. Indeed, CKD-associated mineral bone disease is complex and requires combined therapies for its management and prevention. These treatments include the regulation of phosphate and calcium metabolism, and agents that control serum PTH levels directly. In the majority of cases, combined therapy and individualization of approaches are recommended to attain optimal results.

# Phosphorus metabolism and fibroblast growth factor 23 in chronic kidney disease

*Anip Bansal and Michel Chonchol*

Division of Renal Diseases and Hypertension, Department of Medicine, University of Colorado Anschutz Medical Campus, Aurora, CO, United States

The kidneys play an integral role in bone and mineral metabolism. Serum phosphate concentrations are tightly regulated in healthy individuals through several mechanisms including dietary absorption, bone flux, and renal excretion. Reduced kidney function due to various pathological etiologies leads to compensatory adaptations to maintain normal serum phosphate. Fibroblast growth factor 23 (FGF23) is a bone-derived endocrine hormone that has emerged as a key phosphaturic hormone responsible for regulating serum phosphate.

## Phosphate metabolism in health

The term phosphorus is used interchangeably with phosphate when referring to dietary composition and distribution in the body. However, since phosphorus occurs almost exclusively in anionic form in the body, the term phosphate will be used throughout this chapter.

About 85% of total phosphate is deposited in bone and ~10% in soft tissues, the remaining 2%–3% is found in serum [1]. At a pH of 7.4 the predominant phosphate species are  $\text{HPO}_4^{2-}$  and  $\text{H}_2\text{PO}_4^-$ , and changes in systemic or local pH can modify transmembrane phosphate transport [2]. Serum phosphate levels in adults are maintained in a narrow range of 2.4–4.5 mg/dL via tight regulation of the freely exchangeable pool. Deviations from this normal range—both low phosphate levels, that is, hypophosphatemia, and high phosphate levels, that is, hyperphosphatemia—can lead to altered cellular and organ function manifesting as bone disorders, anemia, tissue calcification, nephrolithiasis, and increased cardiovascular (CV) mortality. Serum phosphate levels, both in

healthy individuals and those with chronic kidney disease (CKD), have a circadian rhythm with a morning nadir and late nocturnal peak [3,4].

Phosphate homeostasis is the physiological process of regulating net phosphate balance. Net phosphate balance refers to the difference between intestinal absorption of phosphate, shift of intracellular phosphate between extracellular and bone storage pools, and urinary and fecal losses. The net urinary losses are determined by reabsorption of phosphate from the glomerular filtrate (60%–80% of filtered phosphate) [1]. Phosphate flux between body compartments is summarized in Fig. 24.1. Dietary phosphate is absorbed in the small intestine predominantly by paracellular diffusion via intercellular tight junctions and to a lesser extent by active transport across the cells. Both intestinal active transport and renal reabsorption in the proximal tubule are mediated by sodium-dependent phosphate cotransporters (NaPi) belonging to the SLC20 and SLC34 gene families. Intestinal NaPi2b transporters are upregulated in response to the active form of vitamin D; that is, 1,25-dihydroxyvitamin D (1,25-VitD) leading to an increase in phosphate absorption [6]. In health, urinary phosphate losses are regulated by highly efficient, constitutively active phosphate reabsorption in the proximal tubules which is mediated by NaPi2a and NaPi2c cotransporters. These channels are regulated predominantly by parathyroid hormone (PTH) and FGF23.

## Phosphate metabolism in chronic kidney disease

One of the earliest abnormalities to occur when kidney function decreases is a sustained reduction in tubular phosphate reabsorption [7]. This has been

FIGURE 24.1 Phosphate flux between body compartments [5]. Source: Reprinted with permission from Blaine J, et al. Renal control of calcium, phosphate, and magnesium homeostasis. *Clin J Am Soc Nephrol* 2015;10(7):1257–72.

shown by demonstrating that as estimated glomerular filtration rate (eGFR) declines, total urine phosphate excretion decreases and fractional excretion of phosphate increases [8]. This is primarily a result of the increase in FGF23 and PTH via their effect of downregulating NPT2a and NPT2c transporters in the proximal tubule. Despite these compensatory changes in the levels of these phosphate-regulating hormones, serum phosphate remains within the accepted normal range until eGFR decreases to less than 20–30 mL/min/1.73 m<sup>2</sup>; that is, hyperphosphatemia is usually not seen in patients with CKD stage 1–3 [9,10]. The change in phosphate, calcitriol, PTH, and FGF23 with worsening predialysis CKD is summarized in Fig. 24.2.

### FGF23's structure, synthesis, and function

The discovery that mutations in the gene encoding FGF23 cause autosomal dominant hypophosphatemic rickets led to a paradigm shift in our understanding of

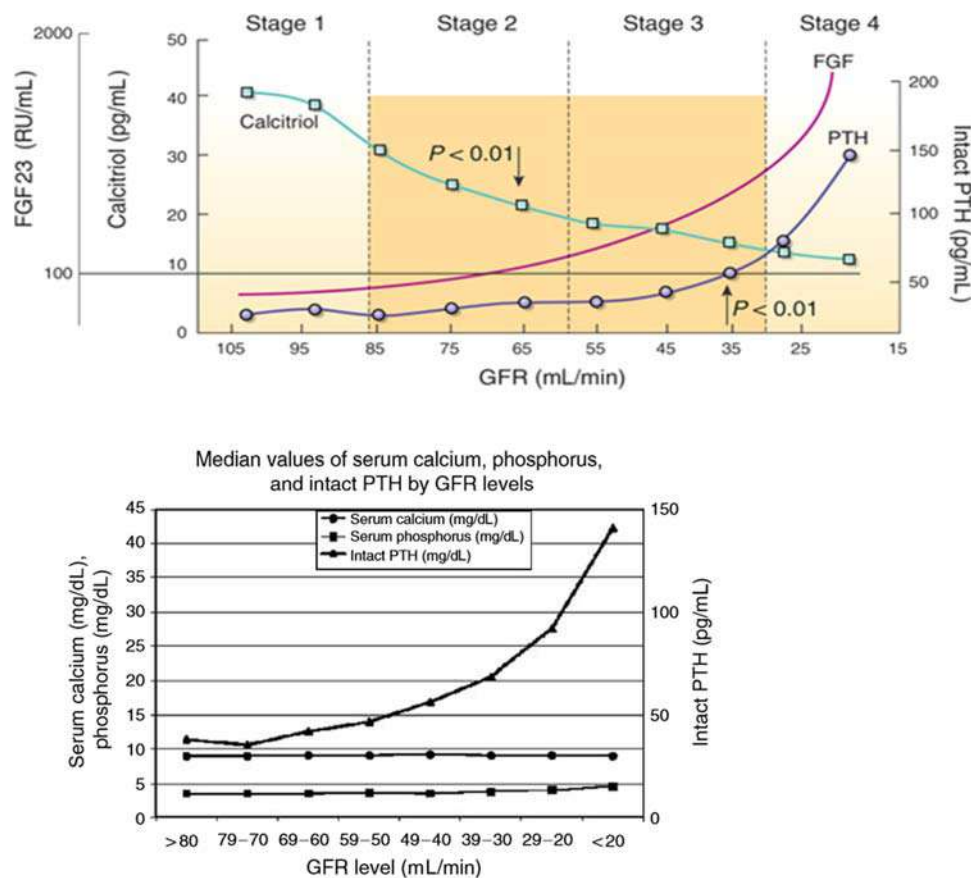

FIGURE 24.2 Changes in phosphate, calcitriol, PTH, and FGF23 with worsening CKD (this will be a combined figure using the figures below with the graph for phosphorus from the second figure superimposed on the first figure) [9]. CKD, Chronic kidney disease; FGF23, fibroblast growth factor 23; PTH, parathyroid hormone. Source: Adapted from Levin A, et al. Prevalence of abnormal serum vitamin D, PTH, calcium, and phosphorus in patients with chronic kidney disease: results of the study to evaluate early kidney disease. *Kidney Int* 2007;71(1):31–8.

the role of FGF23 in normal mineral metabolism [11]. FGF23 has since been shown to be central to the pathogenesis of other rare disorders of phosphate homeostasis including X-linked hypophosphatemia, autosomal recessive hypophosphatemic rickets, fibrous dysplasia, and tumor-induced osteomalacia [12]. These disorders are characterized by kidney phosphate wasting leading to hypophosphatemia, severe rickets or osteomalacia, inappropriately low serum 1,25D levels, growth retardation, and skeletal deformities.

The main sources of FGF23 are skeletal osteocytes, osteoblasts, and bone marrow stromal cells in the skeleton. FGF23 belongs to the FGF19 subfamily of endocrine FGFs and differs from other autocrine FGFs due to its unique C-terminal structure as well as a specific three-dimensional configuration with a lack of a heparin-binding domain that allows it to be secreted systemically [13,14].

The FGF23 gene is located on chromosome 12p13 in humans and encodes FGF23, which is a 32-kDa glycoprotein composed of 251 amino acids. It consists of a hydrophobic signal sequence (24 amino acids), an N-terminal FGF core homology domain (155 amino acids), and a C-terminal domain unique to FGF23 (72 amino acids) [13]. Wild-type FGF23 expression leads to the secretion of both intact FGF23 and cleaved N- and C-terminal peptide fragments.

FGF23 acts on target organs via binding to heterodimeric complexes of FGF receptors (FGFRs) and membrane-bound  $\alpha$ -klotho (klotho) coreceptors that are expressed mainly in the kidney, parathyroid gland, and bone [15]. The N-terminal domain binds to the FGFR, while the C-terminal domain binds to the klotho. Four FGFRs exist and only FGFR1c requires klotho as a coreceptor to bind to FGF23. FGF23 can also exert effects in tissues that express FGFR2 and FGFR4, for example, myocardial tissue, hepatocytes, and neutrophils [16,17]. Binding of FGF23 to its receptor initiates signal transduction through activation of cytoplasmic tyrosine kinases that induce activation of signaling pathways, especially the FGFR substrate 2 (FRS2)—mitogen-activated protein kinase pathway and the phospholipase C $\gamma$ 1 (PLC $\gamma$ 1)—calcineurin—nuclear factor of activated T cells (NFAT) pathway [18]. The obligate role of klotho was demonstrated by showing identical phenotypes result in knockout mice lacking FGF23 (FGF23 $^{-/-}$  mice) and Klotho (Klotho $^{-/-}$  mice) [19]. Soluble klotho, cleaved from the membrane-bound protein, may act as a portable receptor for FGF23.

There are two commercial ELISA assays to measure FGF23, an intact (i) and a C-terminus (c). Since the source of C-terminus FGF23 fragments is FGF23 transcription and subsequent peptide cleavage, high cFGF23 indicates increased transcription of FGF23 with the iFGF23-to-cFGF23 ratio reflecting the relative amount of cleaved FGF23. Combining cFGF23 results with simultaneous measurement of iFGF23 and serum

phosphate can serve as a “liquid” bone biopsy for the assessment of FGF23 dynamics and differentiation of the FGF23 mediated syndromes [20].

FGF23 exerts its effects on the kidney by downregulating NaPi2a and NaPi2c transporters in the proximal tubule [21] leading to increased renal phosphate excretion in response to increased phosphate intake. It is the primary regulator of renal phosphate reabsorption by this mechanism. FGF23 causes decreased production of 1,25-VitD by decreasing conversion of 25-vitamin D to the activated form by inhibiting CYP27B1 (1 $\alpha$ -hydroxylase) and increasing 1,25-VitD inactivation by stimulating CYP24A1 (24-hydroxylase) [21]. This decrease in 1,25-VitD leads to decreased intestinal absorption of calcium and phosphate from dietary sources. The effects of dietary phosphate loading on circulating FGF23 occur independently of changes in serum phosphate.

FGF23 production is stimulated by 1,25-VitD by its binding to the FGF23 promoter region which leads to an endogenous control of 1,25-VitD production via a negative feedback loop [22]. PTH on the other hand stimulates FGF23 directly, while FGF23 inhibits PTH via direct binding to FGFR1c in the parathyroid gland. The decrease in PTH indirectly leads to a further reduction in 1,25-VitD production [23] and decreased release of phosphate from bone.

### FGF23 in chronic kidney disease

Across the entire spectrum of CKD, cross-sectional studies have shown that serum FGF23 levels increase with advancing stages of CKD. This rise in circulating FGF23 levels and the reduction in serum calcitriol levels precede the development of hyperphosphatemia [24,25]. In fact, the rise in FGF23 is seen in very early CKD in outpatients with stable CV disease (CVD) [26]. In rats with antglomerular basement membrane nephritis and CKD stage 2–4, only serum FGF23 and creatinine were significantly elevated 10 days after the onset of CKD; serum PTH levels increased and 1,25-VitD levels decreased only after day 20. This study established that the mechanism of 1,25-VitD deficiency in CKD is a primary excess of FGF23 rather than decreased production due to loss of renal mass [27]. It was hypothesized that increased FGF23 secretion was critical for maintaining normal phosphate balance in early CKD, but with the trade-off of progressive 1,25-VitD deficiency due to elevated FGF23 levels [28]. The current thinking of the pathogenesis of CKD-associated mineral and bone disorders (CKD-MBDs) is summarized in Fig. 24.3 with FGF23 playing a central role.

The mechanism of how kidney disease modulates increased production of FGF23 from bone has been unclear. A recent study that used sampling of multiple

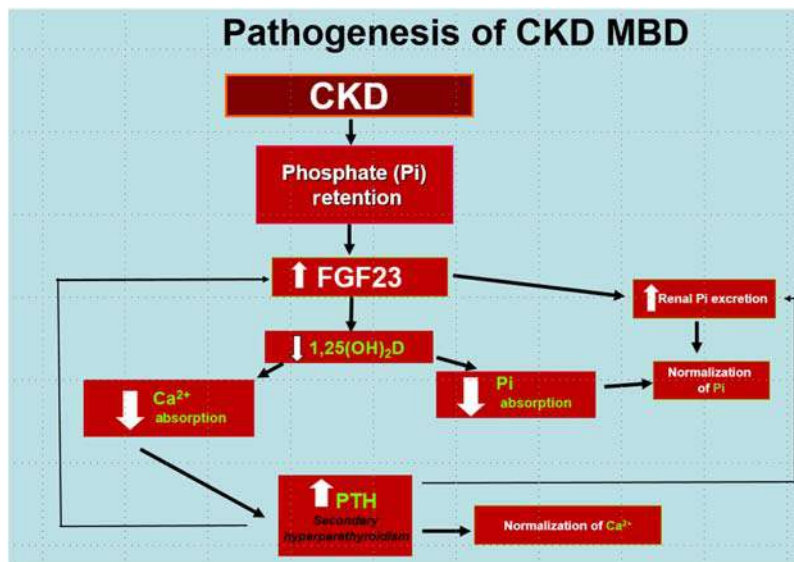

FIGURE 24.3 Pathogenesis of CKD-MBD. CKD, Chronic kidney disease; MBD, mineral and bone disorder.

proteins and metabolites in aortic and renal venous samples from human subjects with a mean eGFR of 66.6 mL/min/1.73 m<sup>2</sup> showed that renal vein glycerol-3-phosphate (G-3-P) had the strongest correlation with circulating FGF23. In mice, exogenous G-3-P stimulated bone and bone marrow FGF23 production through local G-3-P acyltransferase (GPAT)–mediated lysophosphatidic acid (LPA) synthesis. Further, the stimulatory effect of G-3-P and LPA on FGF23 required LPA receptor 1. In humans and mice with AKI (which increases FGF23 levels), there was a rapid increase in circulating G-3-P; and the effect of AKI on FGF23 was abrogated by GPAT inhibition or Lpar1 deletion [29].

Healthy individuals tend to have a higher circulating fraction of FGF23 fragments compared to patients with advanced kidney disease, where almost all the circulating FGF23 is iFGF23 [20,30].

CKD is commonly associated with functional iron deficiency and inflammation. In wild-type mice, chronic inflammation and chronic iron deficiency increased cFGF23 but only modestly increased iFGF23. Acute inflammation dramatically increased iFGF23 levels to a much greater extent in a mouse model of CKD versus wild-type mice suggesting that downregulated or impaired FGF23 cleavage may contribute to elevated iFGF23 in CKD [31]. However, the use of antiinflammatory therapies has not shown a significant effect of FGF23 reduction [32].

### Role of phosphate and FGF23 excess

#### Role of phosphate excess in people without chronic kidney disease

Epidemiological studies in populations without CKD have shown an association of elevated serum

phosphate with all-cause mortality [33,34], CVD [35], and CV mortality [36]. In a cohort of middle-aged women, a higher intake of phosphate was associated with an increased risk of type 2 diabetes [37]. In the Third National Health and Nutrition Examination Survey (NHANES), high dietary phosphate was associated with increased all-cause mortality [38]. Further, in this latter cohort, elevated fasting serum phosphate concentrations were associated with increased mortality, whereas higher nonfasting serum phosphate was not. This may be explained by reduced variability associated with measuring fasting levels [39]. In participants in the multiethnic study of atherosclerosis a cohort free of CVD, higher dietary phosphate intake was associated with increased left ventricular mass in men but not in women [40].

Serum phosphate levels in the high normal range have been associated with incident CKD and end-stage kidney disease (ESKD) in the general population, suggesting it a risk factor for kidney disease [41,42]. While these epidemiological studies suggest an association of serum phosphate with adverse outcomes, no study has shown the benefit of reducing serum phosphate in the general population on clinical outcomes.

#### Role of phosphate excess in people with chronic kidney disease

In an observational study in nondialyzed patients with CKD, elevated serum phosphate levels >3.5 mg/dL were associated with a linear increased risk for mortality, independent of renal function, and other known confounding factors [43]. Similar findings of an association between all-cause and CV mortality with increasing serum phosphate in patients with

CKD stage 3–4 were seen in a British cohort [44]. In a large cohort of prevalent maintenance hemodialysis (MHD) patients, hyperphosphatemia and secondary hyperparathyroidism (SHPT) were significantly associated with mortality and with all-cause, CV, and fracture-related hospitalization [45]. On the other hand, in the Modification of Diet in Renal Disease (MDRD) study, phosphate intake was not tightly linked with serum phosphate concentrations in CKD stage 3–5, and there was no evidence that greater phosphate intake, assessed by 24-hour phosphate excretion, was associated with ESKD, CVD, non-CVD, or all-cause mortality [46].

### Role of FGF23 in people without chronic kidney disease

In the prospective Cardiovascular Health Study (CHS) involving community living individuals >65 years age, high serum cFGF23 levels were associated with all-cause mortality and incident heart failure. This was also observed in people without CKD, although the associations were particularly strong among persons with CKD [47]. In this same cohort, higher FGF23 levels were associated with increased prevalent frailty [48], increased incidence of first infection-related hospitalizations [49], greater left ventricular mass and left ventricular hypertrophy (LVH) [50], and greater risk of nonsudden cardiac death [51], but higher serum FGF23 was not associated with incident peripheral arterial disease [52] or hip fracture risk [53].

In the MESA (Multiethnic Study of Atherosclerosis) study in community-dwelling adults without CKD or CVD, high serum iFGF23 was associated with increased incident atrial fibrillation [54] and increased heart failure with preserved ejection fraction, but it was not associated with increased heart failure with reduced ejection fraction [55] or measures of arterial stiffness [56]. In the Framingham study cohort, high cFGF23 levels were associated with increased mortality but not with vascular function or incident CVD [57].

### Role of FGF23 in people with chronic kidney disease

#### **Mortality**

A prospective study of over 10,000 incident patients with ESKD on HD showed that increased cFGF23 levels were associated with mortality independently of serum phosphate levels and other known risk factors [58]. In a cohort of outpatients with prevalent coronary artery disease in the Heart and Soul study, higher serum cFGF23 levels were independently associated with increased mortality and CV events [59]. In the prospective Chronic

Renal Insufficiency Cohort (CRIC) study of patients with CKD stage 2–4, elevated serum cFGF23 was independently associated with mortality [60]. cFGF23 levels were stable in the majority of patients with CKD, but serial measurements identified subpopulations with up to 15 times higher risk of death [61]. In patients with CKD stage 4–5 in the Homocysteine in Kidney and End Stage Renal Disease (HOST) study, serum cFGF23 levels were strongly and independently associated with all-cause mortality, CV events, and initiation of chronic dialysis [62]. This association between elevated cFGF23 and mortality has also been shown in kidney transplant recipients [63].

#### **Cardiovascular disease**

Patients with CKD have an increased risk of mortality, and this is driven primarily by increased CV events, both of which increase as eGFR declines [64]. The factors associated with increased CV risk are multifactorial with nontraditional risk factors playing a major role. In the above HOST study, serum cFGF23 levels were strongly associated with myocardial infarction and amputations [62]. In the CRIC study, elevated cFGF23 levels were associated with an increased risk of heart failure but not with atherosclerotic events [65]. Furthermore, in the same cohort, a strong association was found between elevated serum cFGF23 and incident and prevalent atrial fibrillation which was substantially attenuated only by adjustment for LVH, atrial enlargement, and heart failure events [66].

A metaanalysis of FGF23 and risks of CV and non-CV diseases found that a difference in FGF23 levels corresponding to the difference between the top and bottom thirds of baseline FGF23 concentrations was associated with a 30% increased risk of MI and stroke, 40% increased risk of CV mortality, and 50% increased risk of heart failure [67]. The observation that these associations are not observed in disorders with a primary FGF23 excess due to monogenetic diseases suggests that these adverse events are not directly mediated by FGF23 but are due to associated confounding factors.

#### **Left ventricular hypertrophy**

LVH is a common complication in patients with CKD and is associated with an increased risk of heart failure, atrial fibrillation, ventricular arrhythmias, and sudden cardiac death. Increased serum cFGF23 levels are associated with LVH in CKD patients [68] and in ESKD patients undergoing MHD [69] and chronic peritoneal dialysis [70]. In CKD patients in the CRIC study, elevated serum cFGF23 levels were shown to be associated with a greater risk of both prevalent LVH and of developing LVH in persons who had normal left ventricular geometry at baseline.

Using animal models, it was shown that FGF23 directly causes cardiac hypertrophy mediated by klotho-independent, FGFR-dependent activation of the calcineurin-NFAT signaling cascade [71]. It was subsequently demonstrated that FGF23 acts on cardiac myocytes via a different receptor, FGFR4, in the absence of its coreceptor in the kidney; that is, klotho. This suggests that selective FGFR4 blockade might be a potential therapeutic strategy to mitigate the cardiac toxicity of FGF23 without interfering with its effect on phosphate homeostasis [17]. FGF23 also induces hemodynamic effects that lead to LVH. These effects may include upregulation of the sodium–chloride cotransporter in the distal convoluted tubule leading to sodium retention and volume overload and increased levels of asymmetric dimethylarginine, a competitive inhibitor of nitric oxide production that impairs vasodilation [15]. In an animal study, circulating klotho deficiency was associated with cardiac hypertrophy and dysfunction; the association of these disorders with FGF23 was only observed when plasma Klotho levels were decreased [72]. A bidirectional effect between cardiac disease and serum FGF23 is suggested by animal models showing that LVH in transgenic mice is associated with an increase in both myocardial and serum intact FGF23 [73].

### ***Vascular calcification and endothelial function***

Although increased phosphate levels appear to play a role in the transition of vascular smooth muscle cells (VSMCs) from a vascular to a mineralizing phenotype, the role of FGF23 in this process is not clear. In the CRIC study, baseline cFGF23 levels were not associated with the severity of coronary artery calcium scores. This was in contrast to the association observed between higher serum phosphate and increased coronary artery calcium even after adjustment for cFGF23 levels. In cultured human VSMCs, elevated phosphate concentrations induced calcification *in vitro*, whereas exogenous FGF23 had no effect on phosphate uptake or phosphate-induced calcification regardless of the phosphate concentration or presence of soluble klotho [74]. CKD is a state of klotho deficiency with a linear decrease in klotho levels as CKD worsens, starting in early CKD [75]. It has been shown in transgenic mice that klotho deficiency causes severe vascular calcification [76]. This process can be ameliorated by klotho, by enhancing phosphaturia, preserving glomerular filtration, and directly inhibiting phosphate uptake by VSMCs.

### ***Progression of chronic kidney disease***

Potential mechanisms by which FGF23 excess may enhance the progression of CKD are not completely understood. In the CRIC study, elevated cFGF23 was

shown to be an independent risk factor for ESKD in patients with relatively preserved kidney function and for mortality across the spectrum of CKD [60]. Serial cFGF23 measurements showed that increasing FGF23 levels are independently associated with the risk of progression to ESKD [77]. Longitudinal study of this cohort showed that mean serum cFGF23 levels increased markedly in the 5 years before the onset of ESKD, while PTH and phosphate increased modestly, and serum calcium levels declined minimally over time [78]. In a prospective cohort of 984 stable kidney transplant recipients, higher serum cFGF23 levels were independently associated with increased mortality and allograft loss independent of serum phosphate and PTH levels [63]. Despite these epidemiological associations, these studies are limited by residual confounding, and FGF23 may just be a marker of the severity of kidney disease rather than a cause of progressive kidney disease.

## **Interventions to target lowering of phosphate and FGF23**

The aim of lowering serum phosphate is to reduce such long-term adverse outcomes as increased mortality and CV disease in CKD. A decline in serum phosphate levels in MHD patients was associated with improved survival in a multinational prospective cohort [79]. Interventions in nondialyzed CKD patients with normal or slightly increased serum phosphate could be considered preventive rather than therapeutic to ameliorate the onset of the pathological cascade that is associated with CKD-MBD [2]. Since dietary phosphate is the major determinant of FGF23 secretion, interventions to reduce intestinal phosphate absorption should lead to lower FGF23 levels. Direct blockade of FGF23 is an investigational approach to ameliorate the adverse effects of this hormone. The overall approach to management of elevated phosphate is summarized in Fig. 24.4.

### **Extracorporeal phosphate removal to lower serum phosphate and FGF23**

Dialytic removal of phosphate averages ~800 mg per HD treatment session. However, the amount removed varies widely among patients, ranging from 300 to 1200 mg per dialysis even with similar doses of dialysis [81]. The amount of phosphorus removed by HD is not dependent on different serum phosphate concentrations but reflects a marked difference between patients in their rate of phosphorus mobilization, mainly from muscle to blood [82]. In a single-center prospective cohort study, increased frequency of HD with short daily treatments

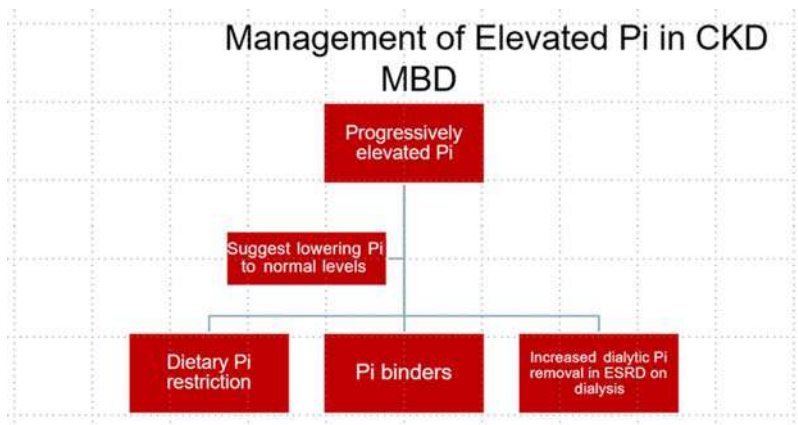

FIGURE 24.4 Management of elevated Pi in CKD-MBD. CKD, Chronic kidney disease; MBD, mineral and bone disorder. Source: Adapted from *Kidney Disease: Improving Global Outcomes. KDIGO 2017 clinical practice guideline update for the diagnosis, evaluation, prevention, and treatment of chronic kidney disease-mineral and bone disorder (CKD-MBD)*. *Kidney Int Suppl* (2011) 2017;7(1):1–59.

led to increased phosphate clearance per week and resulted in a decrease in the use of phosphate binders from 77% to 40% at 12 months [83]. Similar improvements in serum phosphate levels with intensive HD were seen in the Frequent Hemodialysis Network (FHN) trial of daily short HD versus conventional HD and in the FHN nocturnal trial [84]. A post hoc analysis of these two trials showed that lower serum phosphate concentrations led to a decrease in serum FGF23 levels, but this has not been examined in large prospective studies [85]. A metaanalysis of randomized controlled trials on convective therapies using hemodiafiltration versus low-flux HD revealed a net increase in phosphate clearance with convective therapies by 20.8 mL/min [86].

### Oral phosphate binders

A number of phosphate binders are used clinically to lower intestinal phosphate absorption. This also leads to the upregulation of active sodium phosphate cotransporters (NaPi2b) in the small intestine [87] which, by promoting increased absorption, may limit the effectiveness of the binders in CKD patients. Observational studies have shown a survival benefit in MHD patients who use phosphate binders as compared to those not taking these binders [88–90]. The optimal serum phosphate levels that should be aimed for with binders are not known. This question is the subject of ongoing trials, such as the HiLo pragmatic trial that will compare the effects of different serum phosphate targets in MHD patients (NCT04095039).

The KDIGO CKD-MBD 2017 guidelines update recommends restricting the use of calcium-based binders [91]. This recommendation was based on the reduction in CV mortality and the increased survival observed with the use of noncalcium-based binders

[80,92,93]. Although the studies are limited by their small sample size, noncalcium-based phosphate binders given to nondialyzed CKD patients with normal serum phosphate levels appear to lower serum FGF23 more than do calcium-based binders [94–97].

Transcription of FGF23 is reported to be enhanced by iron deficiency [98]. This may provide an opportunity for specific benefits of iron-based phosphate binders. In addition to decreasing intestinal phosphate absorption and providing iron to the body, these binders, by increasing body iron, may reduce FGF23 transcription and thereby decrease FGF23 levels. In a rat model of CKD, sucroferic oxyhydroxide decreased iFGF23 to a significantly greater degree than lanthanum carbonate or sevelamer hydrochloride [99]. A pilot study of MHD patients with hyperphosphatemia showed that treatment with sucroferic oxyhydroxide rapidly reduced serum phosphate with a concomitant decrease in serum FGF23 levels and led to the improvement in anemia with a decreased need for intravenous iron and erythropoiesis-stimulating agents [100].

In a mouse model of CKD, initiation of ferric citrate treatment early in the course of murine CKD lowered iFGF23, slowed CKD progression, improved cardiac function, and significantly improved survival [101]. In nondialyzed CKD patients, ferric citrate can also be used to treat iron deficiency. Short-term use of ferric citrate in CKD 3–5 patients with iron deficiency anemia and serum phosphate >4 mg/dL can replete iron stores, decrease serum phosphate, and reduce serum iFGF23 and cFGF23 [102]. A pilot study showed that the prescription of fixed-dose ferric citrate coordination complex to patients with eGFR ≤20 mL/min per 1.73 m<sup>2</sup> resulted in significant improvements in anemia-related end points and significant reductions in serum phosphate and iFGF23 [103].

## Novel interventions to reduce intestinal phosphate absorption

Nicotinamide, a derivative of niacin, has been shown in high doses to inhibit NaPi2b expression in animal models [104,105]. In MHD patients the use of nicotinamide has been shown to reduce serum phosphate levels comparably to phosphate binders [106] and has an additive effect when given in combination with phosphate binders [107]. In the AIM-HIGH trial the use of extended release niacin in the subset of patients with CKD lowered serum phosphate but did not lower iFGF23 at 3 years [108]. The CKD optimal management with binders and nicotinamide (COMBINE trial) was a randomized trial to test the efficacy and safety of nicotinamide and lanthanum carbonate in isolation or in combination in persons with CKD stage 3b–4. It failed to significantly lower serum phosphate or iFGF23 levels in any intervention group at 12 months [109].

Tenapanor is a nonabsorbable inhibitor of the sodium-hydrogen exchanger 3 (NHE3) in the intestine which has been used to target the predominant mechanism of enteral phosphate absorption via paracellular transport. It blocks NHE3-dependent sodium absorption leading to decreased proton secretion by enterocytes. The reduced intracellular pH leads to a decrease in the permeability of the tight junctions, which, in turn, reduces paracellular phosphate absorption. Short-term use of tenapanor led to dose-dependent reductions in serum phosphate in MHD patients with hyperphosphatemia [110,111]. In one of these studies, following a marked increase in serum iFGF23 in response to withdrawal of phosphate binders, tenapanor significantly decreased serum iFGF23 [112].

## Calcimimetics

Calcimimetics are allosteric activators of the calcium-sensing receptor and reduce iPTH by increasing the sensitivity of the parathyroid gland to serum calcium. In animal models the calcimimetic cinacalcet decreases serum PTH, 1,25-VitD, and iFGF23 leading to hypocalcemia and hyperphosphatemia [113]. In ESKD patients, hyperphosphatemia does not occur in response to cinacalcet treatment, because urinary phosphorous cannot increase substantially in response to the reduction in serum FGF23 and PTH. The use of cinacalcet to treat SHPT in MHD patients has been shown to decrease iFGF23, whereas vitamin D analogs (another treatment for SHPT) increase FGF23; this effect was independent of the modification of PTH [114]. Etelcalcetide is an intravenous calcimimetic recently approved for the treatment of SHPT in MHD patients. It has been shown to reduce serum PTH and iFGF23 more than placebo or cinacalcet in combination with standard-of-care treatment [115]. In

a secondary analysis of these trials, etelcalcetide-mediated reductions in iFGF23 were associated with a decrease in serum calcium, phosphate, and the calcium-phosphate product, but not in PTH. However, the association between the decrease in serum iFGF23 and markers of bone turnover was of borderline and inconsistent significance [116].

## Nutritional management of phosphate and FGF23 excess in chronic kidney disease

There have been no large randomized controlled interventional trials that have tested the effects of modifying dietary phosphate intake or treating to obtain normal serum phosphorus levels on outcomes in any population [82]. However, the prevention and treatment of elevated serum phosphate remain a cornerstone of the management of CKD-MBD.

### Sources of dietary phosphate

Phosphate is ubiquitous in nearly all animal- and plant-derived foods. The content and bioavailability of phosphate in foods and in other sources of ingested phosphate are highly variable. The three major sources of dietary phosphate are the phosphate present naturally in food, phosphate added to food during processing, and phosphate contained in medications and supplements.

### Organic phosphate

For most adults, approximately 20%–30% of dietary phosphorus is obtained from milk and milk products and 20%–30% from meat, poultry, fish, and grains. Naturally occurring phosphates are present mostly as phosphoproteins, phosphate esters, phytates, or phospholipids. These natural sources of phosphate are related to the protein content of these foods and are often referred to as organic sources of phosphate. Vegetables and grains contain a lower amount of phosphate as compared to most meats and milk products [117]. In MHD patients a high protein intake that may be prescribed to prevent or treat protein malnutrition with a concurrent low phosphate intake is associated with the lowest mortality [118]. Thus it is useful to use the ratio of phosphate-to-protein content (mg/g) in protein sources for dietary education, since a lower ratio will lead to lower phosphate intake with adequate protein intake. The lowest ratio is seen with certain animal-derived foods (average, 11 mg phosphate per g protein), including egg whites and pork rinds, whereas whole eggs, dairy products, legumes, and lentils have higher ratios (average 20 mg/g) [119].

Plant-based phosphate in vegetables, grains, and legumes is largely bound to phytates. This phosphate is not as well absorbed as animal-based phosphates because the human intestine does not secrete phytase,

the enzyme that hydrolyzes phytate, thereby freeing phosphate for absorption [117]. Thus, while on average about 60% of dietary phosphate is absorbed by the intestinal tract, this may be lower in people who are vegetarian or ingesting mostly plant-based diets.

### ***Phosphate additives and inorganic phosphates***

The use of processed foods in the modern world has allowed for increased accessibility, increased shelf life, palatability, and convenience. Processed foods commonly have a high phosphate content because of the use of phosphates as a food additive. The most common additives are sodium phosphate, potassium phosphate, calcium phosphate, and salts of orthophosphoric acid diphosphate, triphosphate, and polyphosphate. These are added to food as preservatives, acidifying agents, emulsifying agents, stabilizers, and taste intensifiers [10]. The absorption of phosphate from additives can be as high as 80%–100% compared to 40%–60% from natural foods. The addition of yeast, a leavening agent that contains phytase, leads to further release of phosphate from plant-based foods. This can result in increased phosphate absorption from plant-based foods that normally have low phosphate bioavailability [119]. The phosphorus content in processed foods includes phosphorus naturally found in these food products plus the phosphorus content in the additives, which may increase the total phosphorus intake to 1000 mg/day [117,120]. In Western diets, phosphate additives have been shown to contribute 10%–50% of total phosphate intake [121]. This may be intensified in people from lower socioeconomic groups because they often have an increased proportion of processed foods in their diets [122]. However, a cross-sectional analysis from the MESA cohort did not show that greater intake of foods commonly enriched with phosphate additives was associated with higher serum phosphate levels in people with largely preserved kidney function [123].

Phosphate-containing excipients, used in the formulation of drugs, are found in approximately 11% of frequently used medications. These pose an additional source of phosphate intake that becomes even more significant in patients with kidney disease who have multiple comorbidities and may take many medicines [124].

### ***Inadequacy of food labels and regulatory policy***

A major public health challenge with regard to avoiding excessive dietary phosphate intakes is that phosphate content is not mandated on food labels. Phosphate additives fall under the category of food items that are generally regarded as safe and hence are not required under the mandatory labeling according to the Food, Drug and Cosmetic Act. Furthermore, currently available food composition tables in books and software programs do not accurately reflect the

additional phosphate contained in phosphate additives. The FDA published the updated version of the Nutrition Facts Panel (NFP) in May 2016 [125]. Despite multiple requests, the FDA declined to require phosphate content on the label, because the label is not intended for clinical management of chronic diseases. Implementation of mandatory labeling of phosphate content on packaged foods, drugs, and dietary supplements would help develop reliable dietary assessment tools and guide appropriate diet choices for patients with kidney disease [82]. As indicated earlier, the excessive phosphate intake of many normal people might also adversely affect their health.

### **Dietary therapy for CKD-associated hyperphosphatemia and FGF23 excess**

Traditionally, the indication for control of serum phosphate in CKD patients has been to prevent SHPT and associated bone disease. The emerging evidence for other adverse effects of phosphate in CKD suggests that dietary phosphate restriction could help preserve kidney function, reduce progression of vascular calcification, reduce LVH, decrease serum FGF23, and prevent worsening SHPT. Observational studies of the relationship between dietary phosphate intake and death have shown an elevated risk of mortality with both extremes of dietary phosphate intake [118,126].

Intervention trials of changing intake of phosphate additives have shown mixed results. In a crossover trial in adults with early CKD, increasing phosphate intake by raising consumption of phosphate additives did not increase albuminuria or serum FGF23 levels [127]. A randomized control trial of limiting intake of phosphorus-containing food additives on serum phosphate in ESKD patients led to a decline of 0.6 mg/dL in the intervention group [128]. In patients receiving MHD for >6 months, replacing phosphorus-containing food additives with foods without phosphate additives reduced serum phosphate by an average of 2.2 mg/dL without interfering in the nutritional status [129]. Thus patients with ESKD may benefit more from this intervention.

Due to the potential for lower phosphate absorption with plant-based diets, these diets have been recommended for prevention and treatment of hyperphosphatemia. Although plant-based protein has been shown to help preserve kidney function, this effect could be due to differences in amino acid intake, dietary acid load, or phosphate bioavailability [6]. A crossover pilot trial was conducted to directly compare vegetarian and meat diets with equivalent nutrient composition. This study, conducted in nine patients with a mean estimated GFR of 32 mL/min, led to

lower serum phosphorus and FGF23 levels with the vegetarian diet [130].

Prior guidelines have recommended that patients with CKD stage 3–5 should limit phosphate intake to 800–1000 mg/day as part of the strategy to manage hyperphosphatemia. This intervention has given inconsistent results, and its effectiveness, therefore, has not been proven. This amount of dietary phosphate is higher than the current recommended dietary allowance for the adult general population, that is, 700 mg/day. According to the KDOQI and Academy of Nutrition and Dietetics (AND) Clinical Practice Guidelines for Nutrition in CKD: 2020 Update, in adults CKD stage 3–5 and MHD patients, it is recommended to adjust dietary phosphate intake to maintain serum phosphate levels in the normal range without specifying a target amount [131]. This is similar to the recommendations in the most recent KDIGO guidelines on CKD-associated MBD [80]. It is also suggested that the bioavailability of dietary phosphate sources be considered although this is not supported by clinical evidence [131]. The guidelines advises selecting commercial foods prepared without phosphate-containing additives, choosing natural foods that have low phosphate-to-protein ratios and preparing foods at home using wet cooking methods which can remove up to 50% of the phosphate content of foods [132–134].

Although dietary phosphate restriction may be used by itself in patients with CKD stage 3–4, the reduction serum phosphate achieved is modest. In most if not all CKD stage 5 patients and in chronic dialysis patients, other interventions must be used in conjunction with dietary phosphate restriction. Short-term dietary phosphate restriction tends to reduce serum FGF23 levels in patients with moderately decreased kidney function [135]. This is observed only with very low phosphate diets (<750 mg/day); lowering of serum FGF23 usually requires concomitant use of phosphate binders and very low phosphate diets for a prolonged duration of time [90,136].

### Direct blockade of FGF23 activity

Burosumab, a fully human monoclonal IgG1 antibody against FGF23, was recently approved for the treatment of X-linked hypophosphatemia. It binds circulating intact FGF23 and thereby blocks its biologic effects in target tissues. In an open-label phase II trial in children with X-linked hypophosphatemia, treatment with burosumab improved kidney tubular phosphate reabsorption, serum phosphate levels, linear growth, and physical function and reduced pain and the severity of rickets [137]. Subsequently, in a randomized phase III trial enrolling children aged 1–12 years with X-linked hypophosphatemia,

significantly greater clinical improvement was shown in the severity of rickets and in growth, and biochemistries in the patients treated with burosumab as compared with those continuing on conventional therapy [138].

Two studies have explored the utility of anti-FGF23 antibodies in experimental CKD. In rats with antglomerular basement membrane nephritis and CKD stage 2–4, a single injection of monoclonal mouse antihuman FGF23 antibody was associated with a decrease in serum PTH and an increase in serum phosphorus and 1,25-VitD levels [27]. In 5/6 nephrectomized rats with CKD stage 3–4 given a high-phosphorus diet the use of an antirat FGF23 antibody three times per week for 6 weeks led to sustained decreases in serum PTH, increases in 1,25-VitD levels, and normalization of bone markers. This response was associated with dose-dependent hypercalcemia, marked hyperphosphatemia, aortic calcification, and increased mortality without an effect on ventricular hypertrophy [139]. This paradoxical effect, despite the FGF23 blockade, was attributed to the deleterious effects of hyperphosphatemia, possibly enhanced by the high phosphate diet fed to the rats and progression of kidney failure. It has been speculated that in humans with ESKD, FGF23 blockade in combination with other measures to treat hyperphosphatemia (i.e., dietary and pharmacologic restriction of phosphorus intake and extracorporeal removal of phosphorus) may mitigate or prevent LVH and decrease mortality [140]. However, increased 1,25-VitD with FGF23 blockade might lead to enhanced intestinal absorption of calcium and phosphate and prevent this hypothetical benefit.

Future development of selective FGFR4 antibodies could theoretically abrogate the off-target effects on cardiac myocytes and hepatocytes without affecting phosphate balance. Another theoretical approach would be to use exogenous soluble klotho to bind FGF23 in circulation and minimize activation of klotho-independent pathways.

### Summary

The discovery of FGF23 and its role in rare disorders of hypophosphatemic rickets has led to a rapid expansion in our understanding of its effects on the kidney and the pathways that lead to normal mineral metabolism and its dysregulation in CKD. A wide array of epidemiological data supports the association of elevated serum FGF23 with adverse clinical outcomes. Further research into potential targeted interventions is needed to improve outcomes. Nutritional management of phosphate remains the cornerstone of management of CKD-associated MBDs.

# Vitamin D in kidney disease

*Julia Scialla*

Departments of Medicine and Public Health Sciences, University of Virginia School of Medicine, Charlottesville, VA,  
United States

## Introduction

Vitamin D is a steroid hormone that interacts with the vitamin D receptor (VDR) complexes to affect a broad range of cellular functions [1]. Its most classic functions are in the gastrointestinal tract to promote calcium and phosphorus absorption, in the kidney to promote calcium reabsorption, and in bone to promote the development of osteoclasts that resorb bone. The role of vitamin D in kidney disease has been well recognized since the early 1970s [2,3], but our understanding continues to evolve [4]. Vitamin D is metabolized to both active and inactive compounds in the proximal tubule of the kidney, setting off a cascade of physiologic pathways influencing calcium homeostasis and bone disease. With growing recognition of nonclassical targets of vitamin D and its metabolites, the role of vitamin D in many additional pathways relevant to kidney disease has been postulated. Potential pathways include contributions to hypertension, insulin resistance, cardiovascular complications, and kidney disease progression [5–7]. This chapter will discuss normal vitamin D physiology, including the prominent role of the kidneys in vitamin D metabolism, and our current understanding of the role of dietary and supplemental vitamin D for patients with kidney disease.

## Normal vitamin D metabolism and functions

### Intake and metabolism of vitamin D

Vitamin D is obtained through diet and supplements or produced endogenously after contact with ultraviolet B radiation in sunlight. Vitamin D comes in two major forms, vitamin D<sub>2</sub>, or ergocalciferol, and

vitamin D<sub>3</sub>, or cholecalciferol (Table 25.1) [8]. After ingestion and absorption, vitamin D of either form is converted by cytochrome P-450 enzymes in the liver, such as CYP2R1, to 25-hydroxyvitamin D (25-D) [9]. Conversion in the liver is rapid and unregulated; thus 25-D is the major storage form of vitamin D and currently the most appropriate indicator of vitamin D status in the general population. The vast majority of 25-D circulates in the bloodstream bound to vitamin D-binding protein (VDBP) or albumin [9,10].

Although 25-D is the primary storage form and the target of supplementation, the most potent and active form of vitamin D is 1,25-dihydroxyvitamin D (1,25-D). Like 25-D, 1,25-D can be formed from either D<sub>2</sub> or D<sub>3</sub> and will be referred to collectively throughout this chapter. 1,25-D is formed from 25-D as the result of hydroxylation at the lead (1 $\alpha$ ) carbon. 1 $\alpha$ -Hydroxylation is primarily performed by the cytochrome P-450 enzyme in the mitochondria of the proximal tubule of the kidney, encoded by CYP27B1 [3,11]. First, VDBP or albumin-bound 25-D is reabsorbed in the kidney proximal tubule through specific receptors, megalin and cubilin [12–14]. After absorption, 25-D is converted locally to 1,25-D and reabsorbed into the circulation to exert its hormonal functions. Unlike 25-hydroxylation, conversion to 1,25-D is a highly regulated process. Control is exerted on two major steps: (1) 1 $\alpha$ -hydroxylation by CYP27B1, which produces active 1,25-D, and (2) 24-hydroxylation by CYP24A1, which metabolizes 25-D and 1,25-D to the inactive metabolites 24,25-D or 1,24,25-D (Fig. 25.1) [9,15,16].

Regulation of 1,25-D production and catabolism is under hormonal control by parathyroid hormone, fibroblast growth factor-23, and 1,25-D itself. Parathyroid hormone is a hormone released by the parathyroid gland in response to falling blood calcium levels. Parathyroid hormone restores calcium levels by

TABLE 25.1 Forms and major sources of vitamin D.

Vitamin D form	Common name	Common sources	Comments
Vitamin D <sub>2</sub>	Ergocalciferol	Fungal foods: mushrooms, yeast	Intake form
Vitamin D <sub>3</sub>	Cholecalciferol	Sunlight, fatty fish, cod liver oil, egg yolk, supplemented foods	Intake form
25-Hydroxyvitamin D (25-D)	Calcidiol	Liver hydroxylation of D <sub>2</sub> or D <sub>3</sub>	Major circulating form
1,25-dihydroxyvitamin D (1,25-D)	Calcitriol	Kidney hydroxylation of 25-D	Highly potent active form
24,25-Dihydroxyvitamin D (24,25-D)	—	Catabolic hydroxylation of 25-D	Inactive form
1,24,25-Trihydroxyvitamin D (1,24,25-D)	Calcitroic acid	Catabolic hydroxylation of 1,25-D	Inactive form

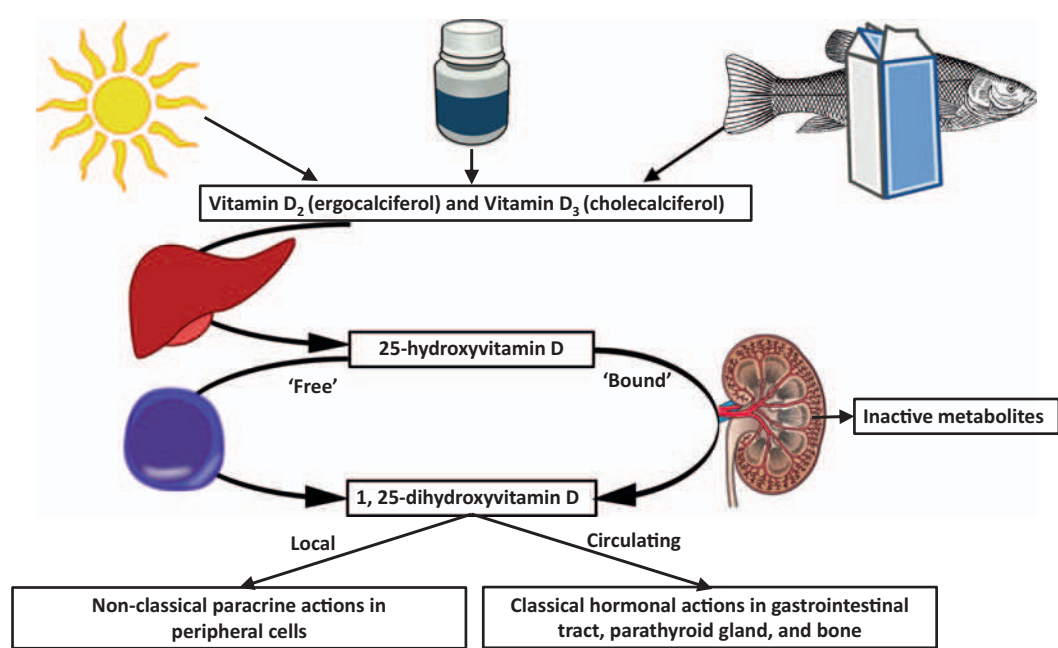

FIGURE 25.1 Simplified overview of normal vitamin D metabolism. Vitamin D is produced in the skin by conversion of 7-dehydroxycholesterol to cholecalciferol in response to ultraviolet B radiation or from the consumption of vitamin D-containing foods and supplements. Cytochrome P-450 enzymes in the liver rapidly convert vitamin D to 25-hydroxyvitamin D, the major circulating form. Most 25-hydroxyvitamin D circulates complexed to VDBP or albumin, which improves its stability and promotes uptake in the kidney via megalin and cubilin proteins. The 1 $\alpha$ -hydroxylase enzyme, primarily expressed in the kidney, then converts 25-hydroxyvitamin D to its most active form 1,25-dihydroxyvitamin D and releases it into the circulation for hormonal functions in target tissues. The kidney also expresses 24-hydroxylase that catabolizes both 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D to inactive forms. Peripheral cells, including white blood cells, can also locally convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D allowing it to bind the vitamin D receptor complex and function as a transcription factor locally. “Free” or unbound 25-hydroxyvitamin D may be more effectively taken up by peripheral cells because it can freely cross cell membranes, although controversy on this point remains. Hundreds of genes have been shown to have a vitamin D-responsive element in their promoter. Not all of these functions are well understood. increasing calcium absorption in the gastrointestinal tract, reabsorbing calcium in the kidney, and mobilizing calcium from bone stores. One mechanism through which parathyroid hormone promotes these actions is by stimulating 1 $\alpha$ -hydroxylation and inhibiting 24-hydroxylation to raise biologically active 1,25-D levels

[17]. In contrast, the bone-derived hormone fibroblast growth factor-23 rises in response to increased levels of 1,25-D and helps lower or stabilize levels by limiting transcription of 1 $\alpha$ -hydroxylase and increasing transcription of 24-hydroxylase [9,16,17]. 1,25-D and 25-D may also induce expression of 24-hydroxylase to

	General Population	Stages G3-4 CKD	End-Stage Kidney Disease

**FIGURE 25.2 Levels of vitamin D, its metabolites, and major regulatory hormones in patients with chronic kidney disease.** Depicted are major active and inactive metabolites of vitamin D<sub>2</sub> (ergocalciferol) and vitamin D<sub>3</sub> (cholecalciferol). Description of major changes in metabolites and regulatory hormones in kidney disease are provided.

control their production [18]. Together these important regulatory steps prevent vitamin D toxicity and maintain vitamin D sufficiency under conditions of varying intake and sun exposure.

Both 1 $\alpha$ -hydroxylase and 24-hydroxylase activity may be reduced in patient with chronic kidney disease (CKD) because the kidney is the primary site of these enzymatic activities. Thus even with normal stores of 25-D, patients with moderate-to-advanced CKD tend to have lower levels of biologically active 1,25-D and the inactive vitamin D metabolites, 24,25-D and 1,24,25-D (Fig. 25.2) [19]. What exactly these metabolites might mean clinically is an area of ongoing investigation. Lower ratios of 24,25-D to 25-D are associated with increased mortality in patients with kidney disease, potentially because these relatively low 24,25-D levels reflect low 1,25-D, low 25-D or because of residual correlation with kidney function leading to confounding [20,21].

### Normal functions of vitamin D in bone mineralization

Vitamin D is a critical hormone-regulating bone mineralization by calcium and phosphorus. Vitamin D contributes to this process by ensuring adequate absorption of these mineral ions from the gastrointestinal tract [22,23]. Underscoring this key role, deficiency of vitamin D due to insufficient diet, inadequate sun exposure, or genetic defects in vitamin D function results in rickets and osteomalacia, bone diseases characterized by impairment of growth in children, and inadequate mineralization of the skeleton at all ages [24–26]. These conditions can generally be reversed or prevented by restoration of vitamin D stores and adequate daily intake of vitamin D. Additionally, genetic conditions in which vitamin D metabolism is impaired can typically be overcome by high dose supplementation with calcium and phosphorus, implying that ensuring absorption of these minerals at typical intake levels is a central role of vitamin D [11,15].

In the gastrointestinal tract, 1,25-D promotes active mineral absorption through enterocytes [22,23].

**TABLE 25.2** Selected proteins induced by 1,25-dihydroxyvitamin D yielding classical effects of vitamin D.

Target tissue	Protein	Effect
Gastrointestinal	TRPV6, calbindin, PMCA1	Increased active luminal calcium absorption
Gastrointestinal	NPT2b	Increased active luminal phosphorus absorption
Kidney	TRPV5, TRPV6, calbindin	Increased active calcium reabsorption from the glomerular filtrate
Bone	RANKL	Mobilize bone mineral by stimulating osteoclasts

RANKL, Receptor activator of nuclear factor kappa beta ligand; TRPV5, transient receptor potential vanilloid 5; TRPV6, transient receptor potential vanilloid 6.

Throughout the small and large intestines, 1,25-D binds to the VDR forming a transcriptionally active complex [1]. This complex interacts with vitamin D–responsive elements in nuclear DNA to increase the transcription of critical transporters that support absorption of calcium and phosphorus. Increased transcription of the protein calbindin helps sequester calcium inside cells and, by increasing its concentration gradient, promotes further intestinal calcium absorption. Relevant transporters and proteins involved in calcium and phosphorus absorption that have been shown to be responsive to 1,25-D include transient receptor potential vanilloid 6 (TRPV6) and the Ca<sup>2+</sup>-ATPase PMCA1 for calcium and sodium-dependent phosphate cotransporter 2b (NPT2b; Table 25.2) [27,28].

In the kidney, 1,25-D promotes reabsorption of calcium and, hence, prevents excess losses in the urine. After being filtered at the glomerulus, calcium is reabsorbed heavily in the proximal tubule of the kidney along with bulk transport of salt and water. Finer regulation of calcium excretion occurs in the thick ascending limb and distal tubule through calcium transporters, such as transient receptor potential vanilloid 5 (TRPV5), calcium ATPases, and Na/Ca exchangers [15]. At these sites, complexes of 1,25-D and its receptor stimulate transcription of proteins involved in

reclamation of calcium from the tubular filtrate. Vitamin D–responsive proteins involved in calcium transport in the kidney include calbindins, TRPV5, and TRPV6 (Table 25.2).

1,25-D has additional effects in bone, which primarily promote bone resorption and mineral release. Specifically, 1,25-D and VDR complexes stimulate transcription of the receptor activator of nuclear factor kappa beta ligand (RANKL) among other bone regulatory proteins (Table 25.2) [28]. RANKL is a factor that stimulates maturation of undifferentiated osteocytes into mature osteoclasts that resorb bone. Through this pathway the direct effect of 1,25-D on bone may be to promote resorption, a process that liberates calcium and promotes remodeling. Bone remodeling can help ensure healthy bone structure through new bone synthesis but can also lead to bone loss if excessive.

### Nonskeletal actions of vitamin D

In addition to its classical hormonal functions on the skeleton, there is an increasing recognition of autocrine and paracrine functions of vitamin D in a variety of cell types. Hundreds of genes are influenced by a vitamin D–responsive element [29]. These genes include those involved in immunity, cell survival, blood pressure regulation, and insulin sensitivity, suggesting potentially broad impacts of vitamin D status on physiological processes that go beyond mineral and bone [29,30]. Some of the most well-established effects of vitamin D are on the innate and adaptive immune systems and the renin–angiotensin system that regulates blood pressure and the glomerular filtration rate in the kidney [31–33]. As a result of these pleiotropic actions, vitamin D deficiency has been implicated in the pathogenesis of numerous autoimmune and infectious conditions, metabolic disease, and cancer [5,34,35]. Some studies investigating genetic polymorphisms in vitamin D pathways also implicate these pathways in the risk of cancer, cardiovascular disease, multiple sclerosis, type 1 diabetes, and skin diseases such as psoriasis, among others [36–40]. To date, rigorous interventional studies do not strongly support treatment with vitamin D for these indications [34,41].

### Vitamin D binding protein and the free hormone hypothesis

Although 25-D bound to VDBP or albumin is most efficiently absorbed and hydroxylated to 1,25-D in the kidney, in other tissues “free” 25-D that is not bound to VDBP or albumin may more effectively enter the cell [21]. Because of its hydrophobicity, “free” 25-D can cross cell and nuclear membranes to interact directly

with the VDR and influence cellular functions in a wide variety of cell types. It is hypothesized, but not proven, that “free” 25-D may be the most relevant form for vitamin D’s autocrine and paracrine effects (Fig. 25.1) [42]. In some studies, “free” 25-D levels correlate more strongly with parathyroid hormone as well, suggesting that “free” 25-D may also be the more active form controlling parathyroid responses [43]. Not all studies support this concept, and more research is needed to fully test this hypothesis and elucidate the potentially distinct effects of bound and “free” 25-D [44]. If true, VDBP may then play an important role in sequestering vitamin D and helping to regulate its activity. Interventional studies have shown that supplementation with high-dose vitamin D raises VDBP levels, which presumably may help to control activity in the vitamin D axis [18]. Another important role of VDBP may be to maintain a stable reservoir of vitamin D.

### Genetics and heterogeneity of vitamin D metabolism

Some support for the free hormone hypothesis comes from genetic studies related to polymorphisms in VDBP. VDBP has been known for decades to have different genetically determined isoforms, each of which has a different binding affinity for vitamin D that results in different circulating total 25-D levels [36,45–47]. Some genetic mutations in the GC gene that encodes VDBP are differentially distributed across different ancestral groups. For instance, the more common single-nucleotide variant (SNP) at rs7041 in individuals of African ancestry results in a VDBP with lower affinity for vitamin D and may result in higher “free” 25-D levels at the same level of total 25-D. An SNP at rs4855 is another commonly described variant that can affect VDBP affinity for 25-D.

Several studies have shown that 25-D levels associate more strongly with outcomes such as mortality and cardiovascular disease in patients of European compared with African descent [48–50]. In addition, African-Americans tend to have higher levels of parathyroid hormone, higher bone density, and different relationships between vitamin D, parathyroid hormone levels, and bone anatomy or metabolism [46,51–55]. It has been postulated that these phenotypic differences may be related to different frequencies of GC gene polymorphisms that modify the proportion of total 25-D that is “free” in different ancestral groups [56,57]. To date, this hypothesis has not been strongly confirmed, and several studies do not support differences in the relationships between total and “free” 25-D by race [58].

Other polymorphisms in vitamin D pathway genes, such as the VDR, have also been shown to modify

associations between 25-D levels and clinical outcomes in a Caucasian population [52]. More work is needed to fully understand differences in 25-D biology according to genotype and to determine if genetically personalized targets or supplementation strategies are needed.

### **Vitamin D physiology in CKD**

Vitamin D metabolism and action is significantly altered by the presence and severity of CKD. As kidney function worsens, circulating levels of both parathyroid hormone and fibroblast growth factor-23 rise [59]. Both of these hormones play an important role in controlling phosphorus homeostasis in CKD by reducing reabsorption of phosphorus in the proximal tubule of the kidney. Increasing levels of these hormones ensure that the kidney is better able to excrete the daily phosphorus load from the diet despite a lower glomerular filtration rate [17]. The prevailing scientific theory postulates that these hormones initially rise to enable phosphorus clearance but have other effects that impair vitamin D metabolism [60,61]. Fibroblast growth factor-23 inhibits the  $1\alpha$ -hydroxylase enzyme and induces 24-hydroxylase resulting in more catabolized 25-D and lower 1,25-D levels in kidney disease [19,62]. As 1,25-D levels fall, the further rise in secreted parathyroid hormone maintains circulating calcium concentrations, but with the consequence of secondary hyperparathyroidism.

Secondary hyperparathyroidism is present in the majority of patients with advanced CKD and end-stage kidney disease. When left untreated, severe secondary hyperparathyroidism results in severe skeletal and growth abnormalities, including bone fragility and fracture, bone tumors, and vascular calcification [63–65]. Interrupting this cascade with supplementation of 1,25-D is one of the most effective methods to prevent and treat severe secondary hyperparathyroidism [66].

### **Detailed sources of vitamin D and burden of vitamin D deficiency**

Vitamin D is an essential nutrient obtained through both dietary and nondietary means. Dietary forms of vitamin D are primarily in the form of vitamin D<sub>2</sub>, or ergocalciferol, and vitamin D<sub>3</sub>, also known as cholecalciferol. Ergocalciferol is a natural plant-based sterol found commonly in mushrooms and many fortified foods in the United States, such as milk, yogurt, and orange juice. Cholecalciferol is a natural animal-based sterol. High levels of cholecalciferol can be found in oily fish, such as salmon, mackerel or cod liver oil, egg yolks, or is generated endogenously in

the skin by the action of ultraviolet B radiation on 7-dehydrocholesterol in the dermis [8].

In adults the recommended dietary allowance of vitamin D ranges from 600 to 800 IUs daily, an intake that is anticipated to yield a circulating 25-D level of at least 20 ng/mL if sun exposure is minimal [67]. These ranges were most recently evaluated and set by the Institute of Medicine (IOM) in 2011 based on optimal levels to maintain bone health for the majority of the population [68,69]. The IOM established the upper tolerable limit at 4000 IUs daily based on such anticipated toxicity as elevated blood and urine calcium, kidney stones, and other extraskeletal calcification [70–73]. However, the IOM targets are not without controversy, and many experts consider these intakes and targets too low [74]. Expert review by the Endocrine Society recommends a level of at least 30 ng/mL for maintenance of bone mineral density and prevention of osteomalacia. This target corresponds to a recommended intake of 1500–2000 IUs daily for adults, with higher intakes for obese adults who sequester 25-D in adipose tissue and have lower levels [75]. A variety of studies evaluating associations between 25-D levels and markers of bone health, including bone mineral density, osteomalacia, and biochemical responses such as rising serum parathyroid hormone, generally support these targets [59,76–78].

In CKD patients, studies estimate that vitamin D insufficiency or deficiency is common, present in about 40%–50% or more of patients [59,79,80]. Prevalence of vitamin D deficiency is modestly higher among those with more advanced disease [79–82]. These estimates depend on the serum cut points used for deficiency, and experts do not unanimously agree [83]. Most of the aforementioned estimates utilize the cut points for insufficiency of <30 ng/mL and deficiency of <15–20 ng/mL as recommended by the Endocrine Society guidelines [75]. Using the IOM-derived serum cut point of 20 ng/mL for sufficiency, the rates of insufficient 25-D at the population level are significantly lower and decreasing over time [70,72,84]. Additionally, many of these studies are conducted in convenience samples and not necessarily nationally representative groups. Nonetheless, CKD patients may be more likely to have vitamin D deficiency as compared to the general population.

Reasons for high rates of 25-D deficiency are multifactorial but may include effects of proteinuria causing loss of vitamin D bound to VDBP in the urine, poor health status with reduced exposure to sunlight, and limited dietary intake. Other risk factors for deficiency in the general population include obesity with sequestration of 25-D in adipose tissue, dark skin pigmentation resulting in less production in the skin, less sun exposure due to geographic locations or institutionalization,

and medications that induce cytochrome P-450 enzymes resulting in increased vitamin D catabolism [8,56,85–88]. Due to the defect in  $1\alpha$ -hydroxylation in the diseased kidney, deficiency of the active 1,25-D form is pronounced and strongly linked to kidney function in patients with CKD [81].

### Outcomes associated with vitamin D deficiency

Observational studies support associations of low 25-D with a wide variety of adverse outcomes, including cardiovascular disease, insulin resistance, cancer, and mortality [5,89]. Several of these studies were conducted in the CKD population [89]. Limitations of most of these latter studies include confounding by dietary intake, physical activity, and health status; hence, making clear conclusions about the cause-and-effect nature of these relationships is problematic. Mendelian randomization is a method that leverages genetically determined differences in vitamin D levels to examine the associations between vitamin D levels and clinical outcomes. These methodological designs can be effective, because the differences in vitamin D levels are due to variations in genes and not to other factors, like lifestyle, that may be difficult to identify or measure. Several Mendelian randomization studies support potentially cause-and-effect relationships between low 25-D and mortality [90]. Although Mendelian randomization is a strong study design, it still may have bias if ancestral background is not well accounted for in the analysis or if there are pleiotropic effects of the genes that could impact outcomes by other pathways.

Clinical trials remain the strongest design to definitively support cause-and-effect relationships. These trials are not always possible to conduct due to cost, the challenges of treating individuals for long periods of time, or the ethical dilemma of withholding treatment when it may be clinically indicated for other reasons such as bone health. With these caveats in mind, clinical trials of vitamin D supplementation have not confirmed these foregoing associations as clearly causal [5]. A recent trial of supplementation with 4000 IU daily of cholecalciferol versus placebo, the D2D trial, did not indicate a benefit to vitamin D supplementation. Patients in this trial were at risk for diabetes based on glucose intolerance but did not necessarily have vitamin D deficiency at baseline. However, in post hoc analyses, patients with severe vitamin D deficiency ( $25\text{-D} < 12 \text{ ng/mL}$ ) who received supplementation did have a lower risk of incident diabetes mellitus [91]. In the DDM2 trial, supplementation with 4000 IU daily of cholecalciferol did not improve insulin secretion or glycemic control in patients with type 2 diabetes [92]. In the large VITAL trial,

supplementation of adults with 400 IU daily of cholecalciferol did not reduce the overall risk of cardiovascular events or new diagnoses of cancer. Prior observational studies more strongly implicated vitamin D deficiency as being associated with poor cancer outcomes as opposed to being associated with new diagnoses of cancer [90]. With this in mind, secondary analyses of VITAL suggested a possible benefit of supplementation on death from cancer, but this result was not prespecified and should be viewed as exploratory [93]. Similar null results were observed for cancer and cardiovascular outcomes in the Vitamin D Assessment Study; but in this study, high doses of vitamin D supplementation were used [93–95]. For bone outcomes, such as bone mineral density and fracture, benefits have also not been clearly demonstrated at all sites [96–101]. Some studies even show evidence for harm with high-dose vitamin D supplementation, with reduction in bone density and increase in fracture and falls [102,103]. The authors hypothesize that this paradoxical effect is due to excessive stimulation of osteoclastic bone resorption by high doses of vitamin D. It is important to acknowledge that in most of these trials of vitamin D supplementation, a broad population of people were targeted, and their responses may not apply to individuals with vitamin D deficiency.

### Supplementation of vitamin D

#### General principles of supplementation

Supplementation with ergocalciferol and cholecalciferol has been growing in the United States over the last decade, resulting in population level increases in serum 25-D levels [104,105]. The impact of supplementation on vitamin D status is somewhat mitigated by the simultaneous activation of vitamin D catabolism [16]. For instance, in studies in which ergocalciferol (vitamin D<sub>2</sub>) is supplemented, serum levels of cholecalciferol (vitamin D<sub>3</sub>) often fall in compensation [106]. Similar phenomena occur with supplementation of cholecalciferol that yields some reduction in serum vitamin D<sub>2</sub> levels, but this may be less marked than with ergocalciferol supplementation. Less potent induction of catabolism is suggested as the mechanism underlying stronger immediate effects of cholecalciferol as compared with ergocalciferol on serum total 25-D in many studies [43,107]. Calcifediol, or 25-D<sub>3</sub>, appears to replete 25-D levels faster than the parent compound D<sub>3</sub> and could be considered the preferred treatment in more resistant patients [108].

Supplemental doses typically range between 400 and 4000 IU daily for disease prevention [109]. Vitamin D is a fat-soluble vitamin and is stored in adipose tissue. For

this reason, repletion of vitamin D levels among patients with higher body mass index (i.e., with greater body fat) can be challenging with more modest effects of supplementation [109]. Supplementation needs may also differ for patients who have darker skin pigmentation that may suppress cutaneous 25-D production and who have less exposure to sunlight due to geographic location, institutionalization, use of sunscreen, or sun avoidance. In the United States, exposure to foods fortified with vitamin D may vary extensively according to a person's dietary patterns or preferences for nonmodified foods. Seasonal variation is also a major factor in the measurement and supplementation of vitamin D, with levels lowest in the winter and highest in late summer in many areas around the globe [88]. Care should be taken to ensure seasonal effects are considered when measuring vitamin D and considering supplementation.

At this time, vitamin D supplementation is most appropriate for patients with vitamin D deficiency. One should avoid long-term, high bolus doses of vitamin D that have been associated with poor outcomes in clinical trials. Additional risks to consider with supplemental vitamin D include hypercalcemia, nephrocalcinosis, and nephrolithiasis [6,73,100,110,111]. Supplementation in individuals without osteoporosis or clinical vitamin D deficiency is currently not recommended by the United States Preventive Services Task Force [112].

### Supplementation of vitamin D in mild-to-moderate CKD

As kidney disease worsens, the capacity of the kidney to perform  $1\alpha$ -hydroxylation of 25-D is diminished. In clinical studies, reduction of  $1\alpha$ -hydroxylase activity begins early in CKD when estimated glomerular filtration rate is modestly reduced and continues to fall through the progression to end-stage kidney disease [60]. This fall is likely the result of rising levels of fibroblast growth factor-23 in kidney disease. The rise in serum fibroblast growth factor-23 acts to help control phosphorus homeostasis as glomerular filtration of phosphorus falls [113]. However, in addition to promoting phosphaturia, the increasing serum fibroblast growth factor-23 inhibits the transcription of  $1\alpha$ -hydroxylase, the enzyme responsible for generating active vitamin D [114]. In contrast, parathyroid hormone, the other major hormone controlling phosphorus excretion, stimulates the  $1\alpha$ -hydroxylase enzyme. Increased parathyroid hormone secretion counteracts the falling 1,25-D and the hypocalcemia that may result. A consequence of this homeostatic response is the development of secondary hyperparathyroidism and related bone disease. As a result of this process, abnormalities of calcium, phosphorus, parathyroid hormone, and bone histology

progressively develop as kidney disease worsens [60,63,115]. For this reason, treatment of the vitamin D axis in CKD may be particularly relevant to prevent severe skeletal complications.

Joint nutritional guidelines from the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative and the Academy of Nutrition and Dietetics recommend supplementation with ergocalciferol or cholecalciferol for insufficiency or deficiency in CKD with goals similar to the general population [116]. No specific guidance is provided on the screening or use of active vitamin D sterols in more advanced CKD. The Kidney Disease: Improving Global Outcomes Clinical Practice Guidelines for CKD—Mineral and Bone Disorder makes a similar recommendation but also suggests evaluating for vitamin D deficiency when parathyroid hormone levels are consistently elevated or rising in CKD. Active 1,25-D and its analogs are not suggested for patients with stage G4–G5 CKD unless there is evidence of severe and worsening hyperparathyroidism [66].

### Vitamin D in prevention of kidney outcomes

Some observational studies support a potential role for vitamin D supplementation in reducing albuminuria, a major risk factor for CKD progression [57,117–121]. In uncontrolled interventions, treatment with cholecalciferol or ergocalciferol reduced proteinuria to a clinically meaningful degree [122–124]. 1,25-D has also been shown to reduce albuminuria or dipstick proteinuria in many small, short-term randomized trials [125–128], although not all studies demonstrate this effect [129]. This potential benefit may be due to modulation of the renin–angiotensin system by vitamin D [31,130]. Some observational cohort studies also support an association between lower serum vitamin D levels and loss of kidney function or development of end-stage kidney disease, a clinically more meaningful outcome [120,131–134]. Results might have been more convincing if the vitamin D assays had focused on free or bioavailable vitamin D or if variations in the gene encoding VDBP (GC) were considered [57,135]. At the time of publication the potential reno-protective effects of vitamin D remain controversial. Despite these seemingly favorable effects, studies to date have been small, and no clinical trials have clearly demonstrated beneficial effects of vitamin D on the progression of kidney disease.

### Vitamin D, secondary hyperparathyroidism, and bone outcomes in mild-to-moderate CKD

Classic metabolic studies demonstrate that repletion of 1,25-D, the formation of which is impaired in CKD, can restore intestinal calcium absorption, mitigate

secondary hyperparathyroidism, and improve related bone histology in patients with mild-to-moderate CKD [136–140]. More recently, treatment of vitamin D insufficiency or secondary hyperparathyroidism with vitamin D has been shown to lower parathyroid hormone in some, but not all [141], controlled and uncontrolled studies [142–144]. Metaanalyses of randomized controlled trials and observational studies confirm these benefits, although effects of 1,25-D may be stronger than for vitamin D<sub>2</sub> or vitamin D<sub>3</sub> [145,146]. Extended release formulations of calcifediol also improve 25-D and lower parathyroid hormone in short-term trials of patients with CKD and were approved for this use by the Food and Drug Administration in 2016 [147]. Whether earlier treatment to prevent secondary hyperparathyroidism in mild-to-moderate CKD can prevent major bone abnormalities and lead to a net benefit in clinical outcome needs to be studied.

### Vitamin D and cardiovascular disease in mild-to-moderate CKD

Despite evidence that vitamin D supplementation can improve vitamin D status, large metaanalyses do not clearly indicate that such supplementation improves markers of cardiovascular disease in the general population. Results from these analyses were the same whether patients had sufficient or insufficient levels of vitamin D at baseline [148]. Major recent trials designed to evaluate cardiovascular disease also did not demonstrate the benefits of supplementation [93,94,149]. Notably, these studies primarily focused on the general population, and results could be different in CKD due to the altered vitamin D physiology.

In CKD, small trials largely show conflicting results on the effects of vitamin D or 1,25-D supplementation on surrogate cardiovascular outcomes, such as vascular stiffness, endothelial function, or cardiac remodeling. In 87 patients with CKD, treatment with either calcitriol or calcifediol for 6 months resulted in modestly reduced aortic pulse wave velocity, a marker of stiffness [129]. However, in another study of CKD patients, supplementation with 2000 IU daily of cholecalciferol or 0.5 µg daily of calcitriol for 6 months did not improve pulse wave velocity in CKD [141]. In contrast, in an additional study of 120 patients with CKD and vitamin D deficiency, supplementation with cholecalciferol for 16 weeks improved vascular function as indicated by increased flow-mediated dilation and reduction in pulse wave velocity [150]. Other small studies also demonstrate improved flow-mediated dilation after

1,25-D [151,152]. Studies of cardiac geometry have been disappointing, showing no improvement in left ventricular mass or geometry in patients with CKD treated with 1,25-D [153,154]. Altogether these studies are limited by small sample sizes and reliance on surrogate outcomes. Larger studies and those focused on clinical outcomes are needed to determine if supplementation with vitamin D in mild-to-moderate CKD can improve cardiovascular outcomes, perhaps via effects on endothelial function or vascular stiffness.

### Formulations of vitamin D in CKD

Limited data are available on the optimal formulations and dosing for treatment of vitamin D deficiency in CKD. A variety of vitamin D regimens have been studied in clinical trials of patients with CKD and found to be safe and effective in studies of modest duration (Table 25.3) [106,142,155,157]. One small, short-term clinical trial demonstrated a more robust response to supplementation with cholecalciferol (D<sub>3</sub>) compared with ergocalciferol (D<sub>2</sub>) using comparable doses; however, vitamin D status was similar among the treatment groups 4 weeks after supplementation [155]. No studies are available demonstrating an optimal regimen or dosing for long-term vitamin D status.

TABLE 25.3 Selected nutritional vitamin D formulations and regimens used in interventional studies for adult patients with mild-to-moderate chronic kidney disease.

Formulation	Dose	Duration
Cholecalciferol	50,000 IUs/week	8–12 weeks with or without maintenance [16,142,155,156]
Cholecalciferol plus calcium	800 IU and 1200 mg daily	24 months [157]
Cholecalciferol	2000 IU daily	6 months [141]
Cholecalciferol	40,000 IU weekly	8 weeks [144]
Cholecalciferol	50,000 IUs/month	3 months [158]
Cholecalciferol	4000 IUs daily for 1 month, followed by 2000 IU daily	3 months [159]
Cholecalciferol	2000 IUs daily versus 40,000 IUs monthly	6 months [160]
Ergocalciferol	50,000 IUs/week	12 weeks [155]
Ergocalciferol	50,000 IUs twice weekly	5 weeks [106]
Ergocalciferol	40,000 IUs/week	12 weeks [123]

## Vitamin D supplementation in special CKD populations

### Vitamin D supplementation in diabetic kidney disease

Patients with diabetes and kidney disease may be an important population for vitamin D monitoring or supplementation. Diabetic kidney disease is accelerated by activation of the renin–angiotensin–aldosterone system. Due to the role of vitamin D deficiency in activating these pathways, maintaining vitamin D function may be more important in this group [57,134]. Randomized controlled trials demonstrate albuminuria reduction with 1,25-D supplementation in diabetic kidney disease [128]. Small uncontrolled studies suggest that nutritional vitamin D (i.e., vitamin D<sub>2</sub> and vitamin D<sub>3</sub>) may also convey this benefit, but most of the studies are short term [124,161]. Longer term trials of vitamin D and 1,25-D supplementation evaluate the impact on more clinical kidney outcomes.

### Vitamin D supplementation in nephrotic syndrome

Vitamin D circulates bound to albumin and VDBP, both of which partially cross the normal glomerular filtration barrier in the kidney. Vitamin D, in complex with VDBP, is reabsorbed in the proximal tubule as discussed in detail in Section 1.1. However, in the nephrotic syndrome, the glomerular barrier is disrupted, leading to a marked increase in flux of many serum proteins into the urine, including VDBP and albumin. The capacity of the proximal tubule to reabsorb increased albumin and VDBP is overwhelmed and large amounts of vitamin D are lost in the urine. Vitamin D deficiency has been noted in patients with the nephrotic syndrome for over 4 decades [162–164]. In severe cases, osteomalacia and hypocalcemia are evident [115]. Lower 25D levels also contribute to secondary hyperparathyroidism [165]. Despite wasting of VDBP and vitamin D in the urine, supplementation with vitamin D can improve deficiency based on longitudinal observations [164].

### Vitamin D supplementation in advanced CKD and end-stage kidney disease

In end-stage kidney disease, due to deficits in 1 $\alpha$ -hydroxylase activity that are driven by rising fibroblast growth factor-23 and renal scarring, it is likely that repletion of 25-D stores may not correct 1,25-D deficiency. Despite this concern, treatment with nutritional vitamin D in patients with end-stage kidney disease on dialysis has been studied because of the potential

peripheral conversion to 1,25-D or direct effects of 25-D itself. In several trials and observational evaluations, including patients with end-stage kidney disease on dialysis, nutritional vitamin D can raise circulating 25-D [32,166–170]. Nutritional vitamin D may contribute to an increase in serum 1,25-D and lowering or stabilization of parathyroid hormone in some [167,171–173], but not all, studies [168–170]. Thus far, however, these changes have not translated into clinical improvement in vascular function, physical functioning, quality of life, or other important outcomes [32,168,169].

Supplementation with 1,25-D and other active vitamin D sterols is a major feature of therapy for abnormal bone and mineral metabolism in advanced CKD and end-stage kidney disease. 1,25-D sterols can lower parathyroid hormone levels toward normal and prevent severe bone complications [5,66,174,175]. The effects on other outcomes such as cardiovascular disease and mortality have not been proven in clinical trials.

After kidney transplantation the stimulus for fibroblast growth factor-23 production is reduced, and 1,25-D levels can again rise. However, after years of parathyroid overstimulation, irrepressible hyperplasia of the gland may have developed, and parathyroid hormone may not fully normalize despite restoration of normal 1,25-D, a state often termed “tertiary hyperparathyroidism” [176]. Practitioners prescribing 25-D and active vitamin D sterols in the posttransplant setting must be aware of changes in the vitamin D–parathyroid hormone axis in their patients to avoid hypercalcemia and hypophosphatemia as a result of tertiary hyperparathyroidism.

### Vitamin D supplementation in pediatric kidney disease

In children with CKD, additional consideration must be given to the growing skeleton. Vitamin D deficiency and resulting secondary hyperparathyroidism in children can lead to abnormal bone mineralization and high bone turnover disease similar to adults. In children, vitamin D deficiency also causes abnormalities in the growth plate that also result in growth restriction and deformity, a condition known as rickets [24,25]. The effects of vitamin D on the bone and mineral hormonal axis, including parathyroid hormone, and the risk factors for vitamin D deficiency appear similar in children and adults [165,177]. Few large, well-conducted studies are available in children with CKD to differentiate management as compared with adults, and recommendations for supplementation and treatment are similar to the management in adults [66,178].

Potential benefits with regard to treatment and prevention of secondary hyperparathyroidism are probably

similar in children and adults [177,179]. For nonskeletal outcomes, such as kidney disease progression or albuminuria, associations appear similar in children and adults although there is no support for these effects yet from clinical trials [120].

### Current controversies and summary recommendations

There is still no agreement on target levels and optimal intake of vitamin D in the general adult population. Observational studies and clinical trials have evaluated different populations and end points making a meaningful compilation of results challenging. Overall, few studies have definitively demonstrated nonskeletal benefits of vitamin D supplementation. Benefits of modest-to-moderate doses of vitamin D supplementation on bone may only accrue to those with documented deficiency or insufficiency and in cases where large boluses of vitamin D are not given. The United States Preventive Services Task Force currently cites insufficient evidence to support vitamin D screening or supplementation for asymptomatic adults in the United States [112,180]. How to apply these recommendations to patients with kidney disease is unclear.

In kidney disease, unique considerations include the increased risk of 25-D deficiency among those with heavy proteinuria and the inadequate metabolism of 25-D to 1,25-D resulting in secondary hyperparathyroidism. In the context of CKD stages 1–5, treatment of 25-D deficiency may help lower elevated serum parathyroid hormone, but the long-term effects on prevention of refractory hyperparathyroidism or kidney-related bone disease is not well established. In end-stage kidney disease, treatment with 1,25-D compounds can control secondary hyperparathyroidism and prevent severe skeletal abnormalities, but there are also dose-limiting toxicities such as hypercalcemia and vascular calcification. Few studies are available that have examined the effects of 1,25-D compounds on such clinical outcomes as fracture, cardiovascular disease or mortality in CKD patients. With alternative agents, such as calcimimetics, available to control secondary hyperparathyroidism in end-stage kidney disease, more studies of 1,25-D are needed.

Chronic kidney disease (CKD) commonly alters the biochemistry, metabolism, and nutritional requirements for many vitamins and enhances the likelihood of abnormal vitamin function. Both deficiencies and abnormally high levels of vitamins may occur in patients with renal failure. These abnormalities are reviewed in this chapter. Since the last edition of this book, new research has emerged regarding, among other matters, vitamin intake, interference of phosphate binders with intestinal vitamin absorption, vitamin K status in CKD, and the use of vitamins in critically ill patients. Moreover, the recent KDOQI Clinical Practice Guidelines (CPGs) for nutrition in CKD address vitamin supplementation for CKD 3–5D patients [1]. These guidelines are addressed in this chapter. Vitamin D nutrition is reviewed elsewhere (Chapter 23: Calcium, Phosphate, PTH, Vitamin D and FGF-23 in CKD-Mineral and Bone Disorder, and Chapter 25: Vitamin D in Kidney Disease) and will not be addressed in this chapter, and vitamin needs in patients with acute kidney injury (AKI) are also discussed in Chapter 35, Metabolic Management and Nutritional Support in Acute Kidney Injury.

*Note:* Some terms in this chapter regarding the dietary needs of a nutrient are defined as follows: the recommended dietary allowance or recommended daily allowance (RDA) refers to the average daily dietary intake of an essential nutrient that is sufficient to meet the requirement for that nutrient in nearly all (97%–98%) of healthy individuals of a given life stage and gender [2]. When the RDA cannot be determined,

an “adequate intake” (AI) may be used. The AI refers to the recommended average daily intake level that is assumed to be adequate and which is based on observed or experimentally determined approximations or estimates of the nutrient intake by a group or groups of apparently healthy people. RDA and AI are mainly used in the United States. The estimated average requirement (EAR) is the average daily nutrient level estimated to meet the requirements of half the healthy individuals in a given life stage and gender group. It is usually used in Europe [3,4]. Some papers refer to the recommended dietary intake (RDI) or dietary reference intake (DRI) from local guidelines without being more precise or specific.

### Vitamin A, physiology, biochemistry, and nutritional status in chronic kidney disease patients

#### Vitamin A physiology and biochemistry

Vitamin A is composed of several compounds, including retinol and the biologically active retinoids, which have a common structure consisting of four isoprenoid units (20 carbons) with five double bonds (Table 26.1) [5]. Retinol, retinoic acid, and retinal are the main bioactive retinoic compounds. Since the 1990s, the accepted units for the quantification of vitamin A have changed from international units (IUs) to retinol equivalents (REs), where 1.0 IU = 0.3 µg RE [6]. Carotenoids, which are 40-carbon compounds, may

TABLE 26.1 Physicochemical and clinical characteristics of vitamins.

Vitamin	Main compound	Solubility	MW	Protein binding in plasma	HD losses	Peritoneal losses	Body stores	Toxicity <sup>a</sup>
A	Retino	Lipid	286	RBP + prealbumin	None	Controversial <sup>b</sup>	Large	Yes
E	$\alpha$ -Tocopherol	Lipid	431	Lipoproteins	None	Small	Small	Possible
K	Phylloquinone (K1)	Lipid	451	Lipoproteins	NA <sup>c</sup>	NA <sup>c</sup>	Small	No
B1	Thiamine	Water	337	Albumin	13–40 mL/min <sup>d</sup>	Low	4–10 days	No
B2	Riboflavin	Water	376	Weak albumin, IgG	27–52 mL/min <sup>d</sup>	High	2–3 months	No
B6	Pyridoxine	Water	169	Albumin	54 mL/min <sup>e</sup>	= or <urinary excretion	3–4 months	Yes
B12	Cyanocobalamin	Water	1355	Transcobalamin II	Controversial <sup>f</sup>	None	Years	NA <sup>c</sup>
C	Ascorbic acid	Water	176	No	80–280 mg/session <sup>d</sup>	40–56 mg/day	3–4 months	Yes
Folates	Pteroylglutamic acid	Water	441	No	135 mL/min <sup>e</sup>	1/3 of RDA	>1 year	Yes
Niacin	Nicotinic acid	Water	123	Weak	Very low	NA <sup>c</sup>	2 months	NA <sup>c</sup>
Biotin	Biotin	Water	244	Weak	52 mL/min <sup>d</sup>	NA <sup>c</sup>	50 weeks	None
Pantothenic acid	Pantothenic acid	Water	219	NA <sup>c</sup>	30 mL/min <sup>d</sup>	NA <sup>c</sup>	Several weeks	None

HD, Hemodialysis; MW, molecular weight; RBP, retinol-binding protein.

be biologically active and are vitamin A precursors. Variable quantities of carotenoids are converted to retinol; this conversion is regulated according to the body vitamin A levels [7]. The *allo-trans*- $\beta$  carotene is the main bioactive carotenoid. Retinoids and carotenoids are fat soluble and are predominantly found in foods derived from animals for the retinyl esters and from vegetables for the carotenoids [8]. During digestion, retinyl esters are hydrolyzed in the intestinal lumen by pancreatic lipase. Retinol and carotenoids are incorporated into micelles and absorbed by enterocytes, where  $\beta$ -carotene is converted to retinol. Retinol is esterified, combined in chylomicrons, and broken down into chylomicron remnants in the lymphatic system by lipoprotein lipase. Hepatic cells incorporate the chylomicron remnants through apolipoprotein (apo)-E or B receptors. A significant part (10%–40%) of the absorbed retinoids are oxidized or conjugated and excreted into bile and urine.

At least 50% of the retinoid compounds are transferred into the perisinusoidal stellate cells of the liver where they are stored as retinyl palmitate and other retinyl esters. In plasma, retinol is largely bound to apo-retinol-binding protein (RBP-4), a 21.3-kDa protein primarily synthesized in the liver and adipose tissue. This equimolar complex is bound to prealbumin (also called

transthyretin) and delivered to the target where it binds to RBP cell-surface receptors. Retinol is incorporated into the cell, whereas the carrier protein, apo-RBP, is released and catabolized by the kidney. At the cellular level the active form of vitamin A is all-*trans*-retinoic acid, synthesis of which is tightly regulated [9]. The physiological effects of vitamin A are mediated through the retinoic acid nuclear receptors and retinoid X receptors, which belong to the same nuclear receptor superfamily as the vitamin D receptor. Several medications may interfere with vitamin A metabolism or actions. These are summarized in Table 26.2. Plasma vitamin A is usually measured by high-pressure liquid chromatography (HPLC), which has replaced older colorimetric methods. Vitamin A is necessary for normal nocturnal vision; it plays a role in the immune response, in the differentiation of epithelial cells, and the morphogenesis of solid organs, including the kidney, and it has antioxidant properties [10,11]. Because 13-*cis*-retinoic acid promotes cellular differentiation, it has been used to treat acute promyelocytic leukemia [12]. Large-scale clinical trials failed to demonstrate a benefit of large doses of retinol and carotenoids for the prevention of cancer or cardiovascular (CV) disease [13]. An increased death rate was actually reported in patients given vitamin A supplements, which may be attributed to the prooxidant effects of carotenoids [7].

**TABLE 26.2** Medicines and other substances that may interfere with vitamin metabolism and may contribute to vitamin deficiency.

Interactions of vitamins with drugs		
Vitamin	Interacting medication	Effect of interaction
Vitamin A	Tetracyclines	Risk of intracranial hypertension
	Antacids	Increase of their efficacy
	Anticoagulants	Risk of bleeding
	Bile acid sequestrants	Reduces intestinal vitamin A absorption
	Statins	Increase vitamin A levels in the blood
	Doxorubicin	Vitamin A enhances its action
	Orlistat	Reduces intestinal vitamin A absorption
	Retinoids	Toxicity (nausea, vomiting, blurred vision, etc.)
Vitamin E	Cyclosporine	Vitamin E increases intestinal cyclosporine absorption
	CYP3A4 substrates	Vitamin E reduces their effectiveness through acceleration of their breakdown
	Anticoagulants/antiplatelets	Vitamin E enhances their effects
	Statins	Vitamin E decreases their effectiveness
Vitamin K	Cephalosporins, sevelamer	Reduces the intestinal absorption of vitamin K
	Phenytoin	Interferes with the metabolism of vitamin K
	Warfarin	Its activity is antagonized by vitamin K
Vitamin B1 (thiamine)	Phenytoin, penicillins, cephalosporins, aminoglycosides, tetracycline derivatives, loop diuretics, fluoroquinolones, sulfonamide derivatives, trimethoprim	Long-term use may deplete thiamine
Vitamin B6 (pyridoxine HCl)	Levodopa	Decreases effectiveness of levodopa; increases Parkinsonian symptoms
	Phenytoin	Increases risk of seizures
	Isoniazid, penicillamine, cycloserine, ethionamide, and theophylline	Blocks synthesis of pyridoxine-L-phosphate
Folic acid	Methotrexate	Folic acid supplementation reduces toxicity without affecting efficacy
	Antacids, H2 blockers, proton pump inhibitors, bile acid sequestrants, carbamazepine, NSAIDs, sulfasalazine, and triamterene	Decrease folate intestinal absorption
Vitamin B12	Anticonvulsants, chemotherapy medications, colchicine, bile acid sequestrants, H2 blockers, metformin, and proton pump inhibitors	Reduces B12 levels
Vitamin C (ascorbic acid)	Aspirin/NSAIDs	Increases urinary excretion of vitamin C
		Vitamin C increases the drug blood levels
	Acetaminophen	High vitamin C doses reduce urine excretion
	Aluminum-containing antacids	Vitamin C increases aluminum absorption
	Barbiturates	Decrease the effects of vitamin C by increasing its urinary excretion
	Chemotherapy drugs	Vitamin C interferes with chemotherapy agents
	Nitrates	Vitamin C reduces tolerance to nitrates
	Oral contraceptives/hormone replacement therapy	Vitamin C raises estrogen levels
	Protease inhibitors	Vitamin C lowers plasma levels of protease inhibitors
